

WELCOME TO

HOW IT WORKS BOOK OF

DINOSAURS

At first, dinosaurs seem like the product of a wild imagination – how could such weird and wonderful creatures ever have existed on our Earth? Before the extinction event that changed their world forever, dinosaurs and their reptilian relatives of the sea and sky ruled the prehistoric world. From Allosaurus to Zuniceratops, travel back in time to the age of the dinosaurs with the How It Works Book of Dinosaurs and discover the "terrible lizards" for yourself. We've gathered together some of the most amazing creatures and got right under their skins so we can demonstrate to you how they work. Did the Tyrannosaurus rex hunt or scavenge? Why did herbivores grow so massive? Find out how the dinosaurs survived and thrived, about the mass extinction that ended it all and what the dinosaurs left behind for us to find.

HOWIT WORKS BOOK OF CONTENTS

008 The amazing creatures that walked the Earth

The prehistoric

038 A to Z of the dinosaurs

046 What was a dinosaur?

048 How did the dinosaurs' world evolve?

050 Where did dinosaurs live?

060 The dinosaurs' neighbours

Dinosaurs

064 What's inside a dinosaur egg?

066 The world's biggest dinosaurs

070 Dinosaur defence

072 The cleverest dinosaur

074 Diplodocus

076 Triceratops

078 Velociraptor

080 Stegosaurus

082 Tyrannosaurus rex

084 Brachiosaurus

086 Ankylosaurus

088 Apatosaurus

090 Marine reptiles

092 Plesiosaurus

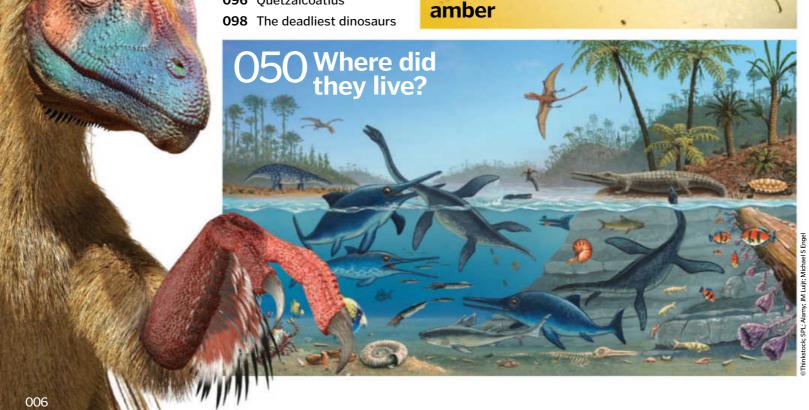

094 Pterosaurs

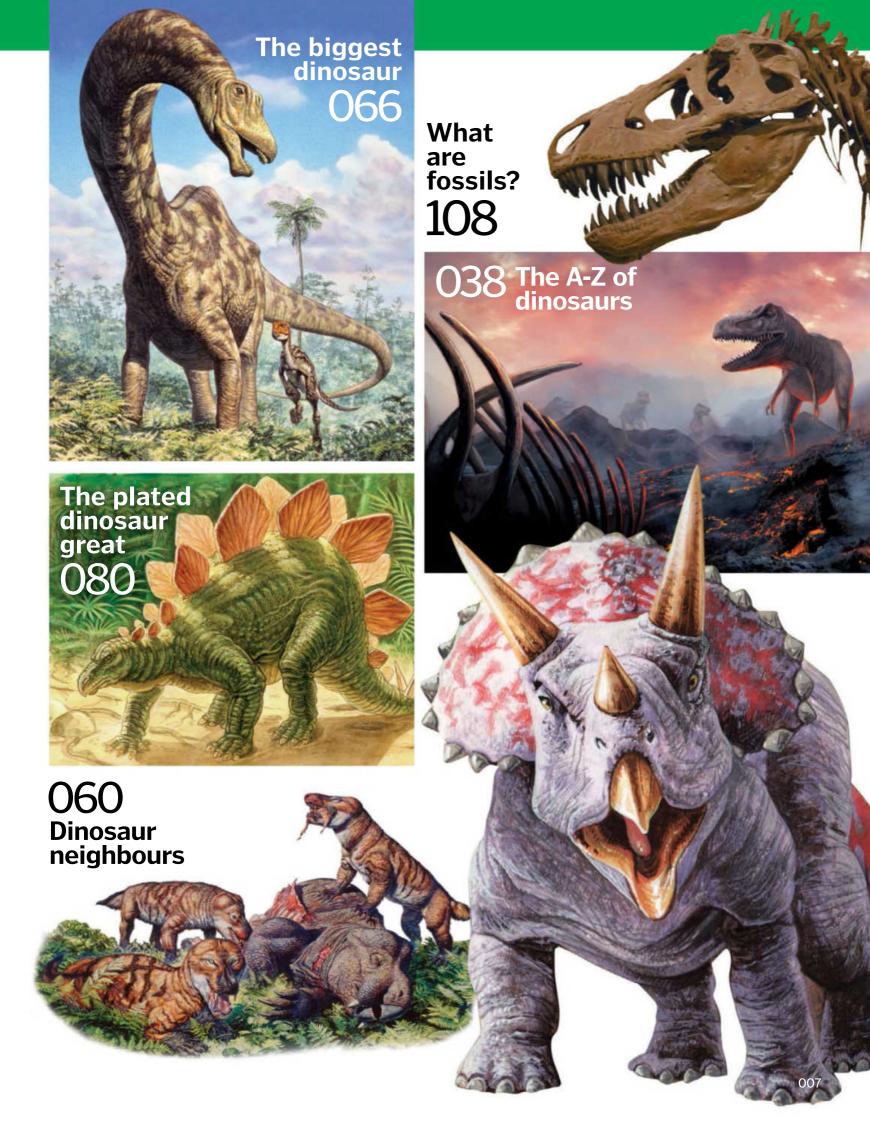

096 Quetzalcoatlus

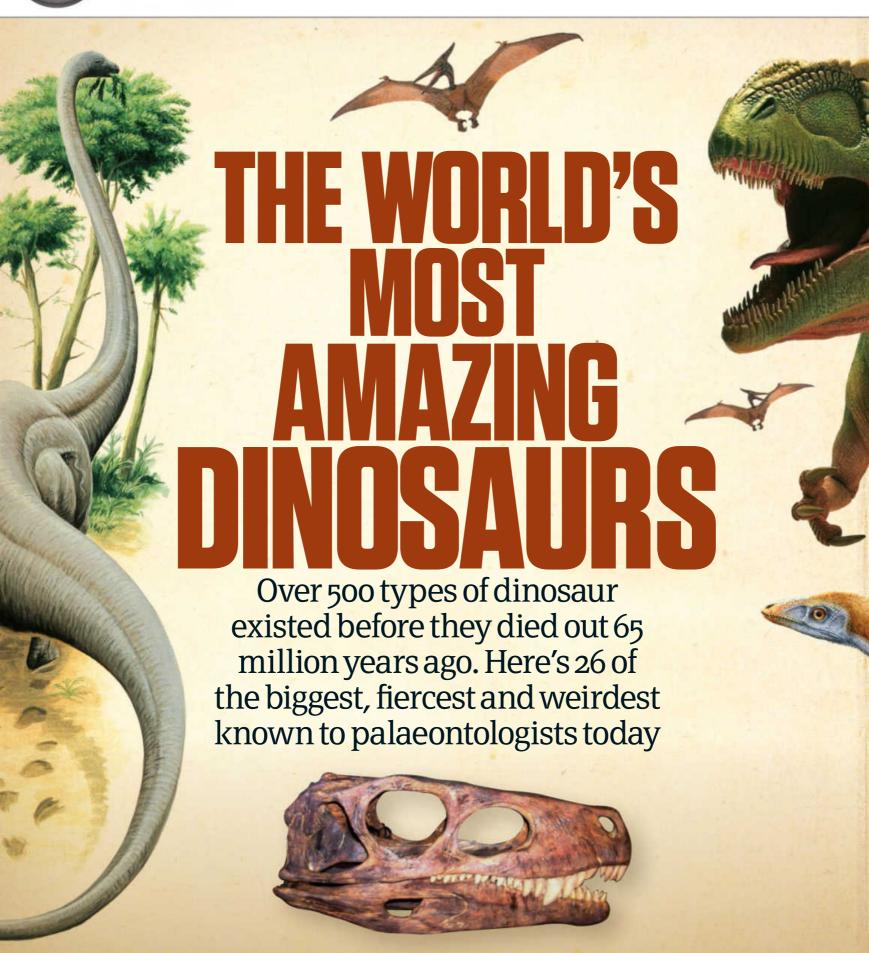

Dinosaurs' legacy

106 Death of the dinosaurs

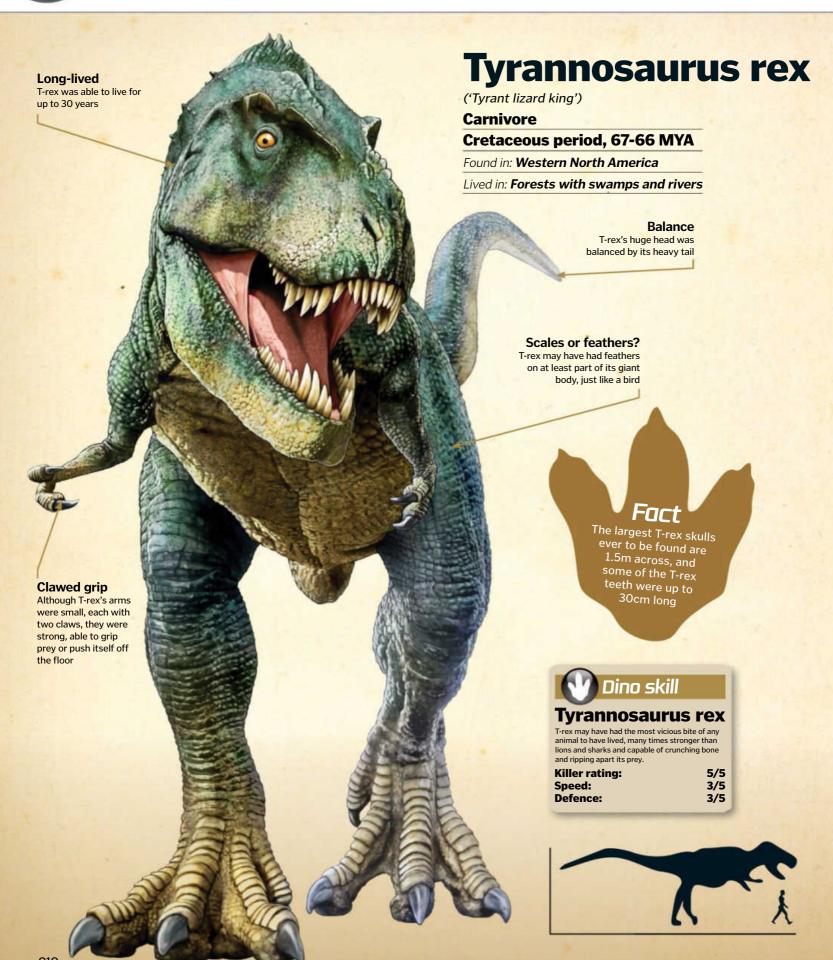

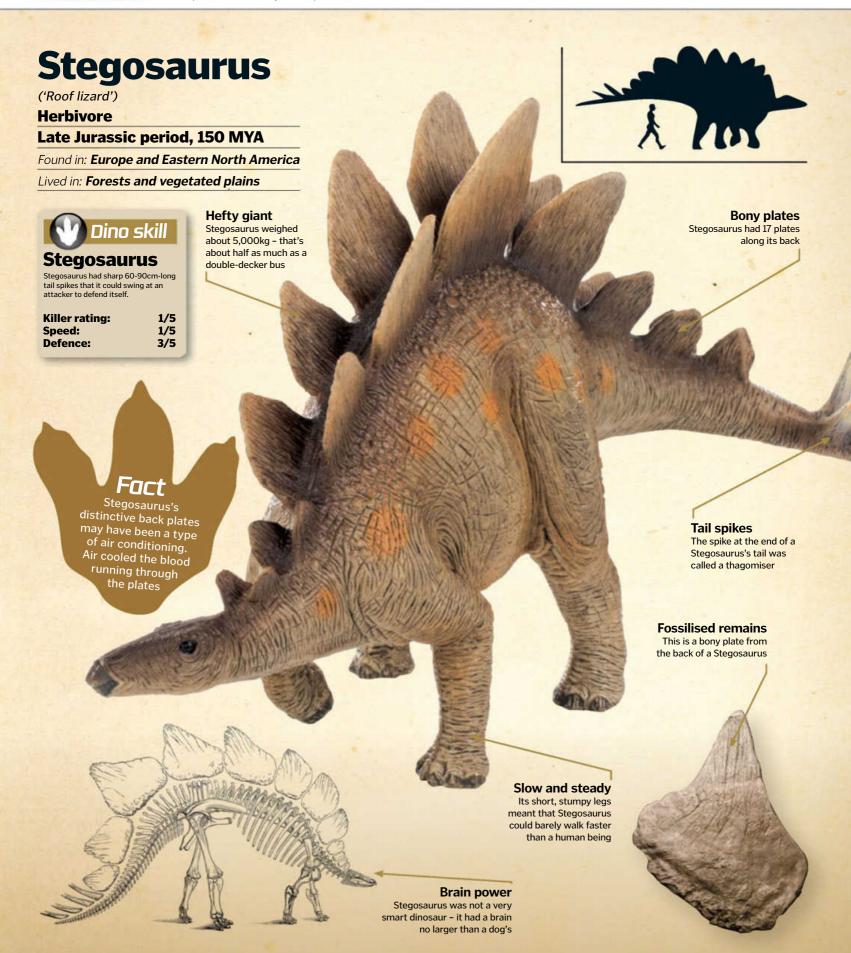

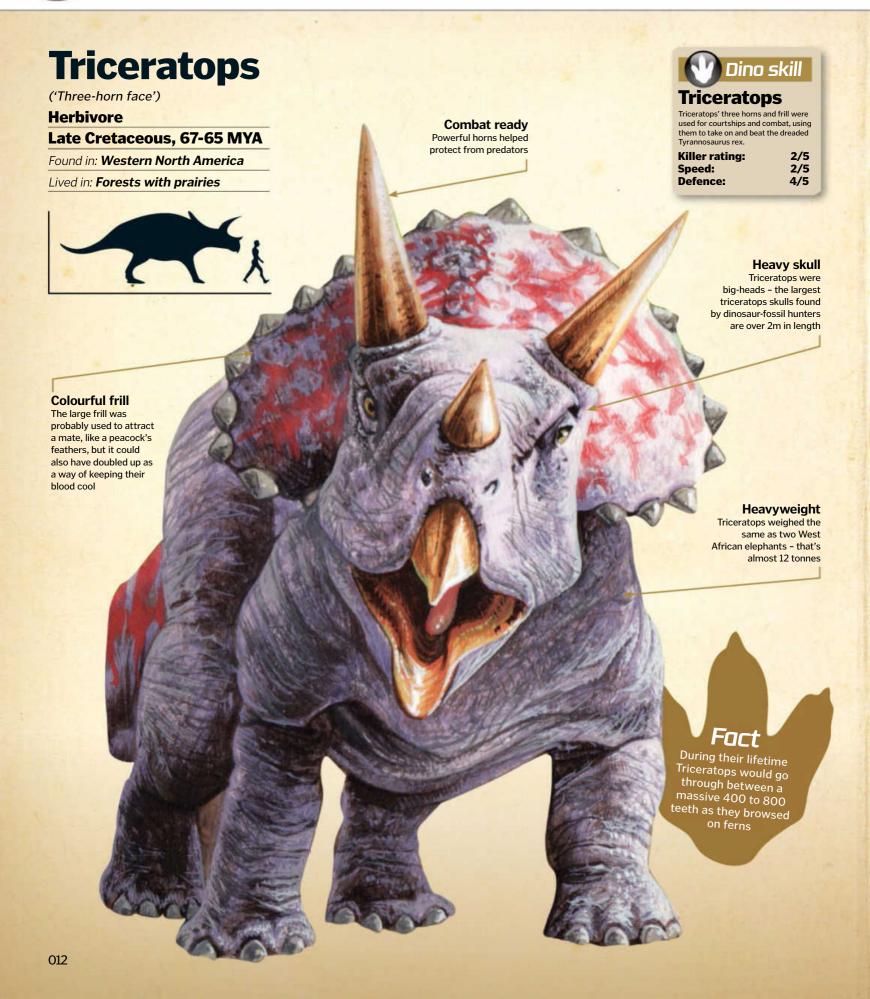

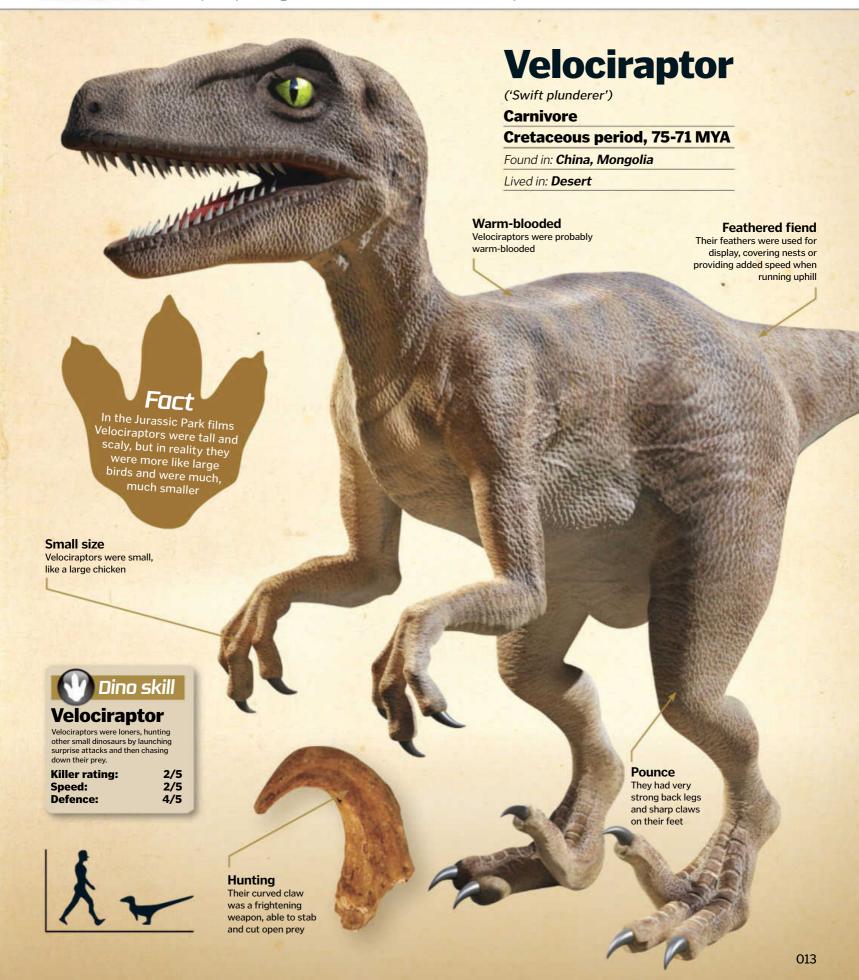

Brachiosaurus

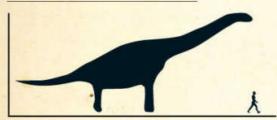

('Arm lizard')

Herbivore

Jurassic period, 150 MYA

Found in: North America

Lived in: Forests

Fact

Brachiosaurus constantly ate. It's thought that it ate between 200 and 400kg of plants every day – that's like eating 400 to 800 lettuces

Small skull

Brachiosaurus had a tiny head

Dino skill **Brachiosaurus**

Brachiosaurus just spent its day lumbering around, so wasn't particularly skilful, but it was so large that no predator could harm it.

Killer rating: 1/5 Speed: 1/5 **Defence:** 4/5

Foraging

Brachiosaurus may have often held its long neck parallel to the ground to sift through the undergrowth for food, as well as to reach up to leaves on trees

Earth-shaker

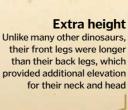

Adult Brachiosaurus weighed over 100 tonnes

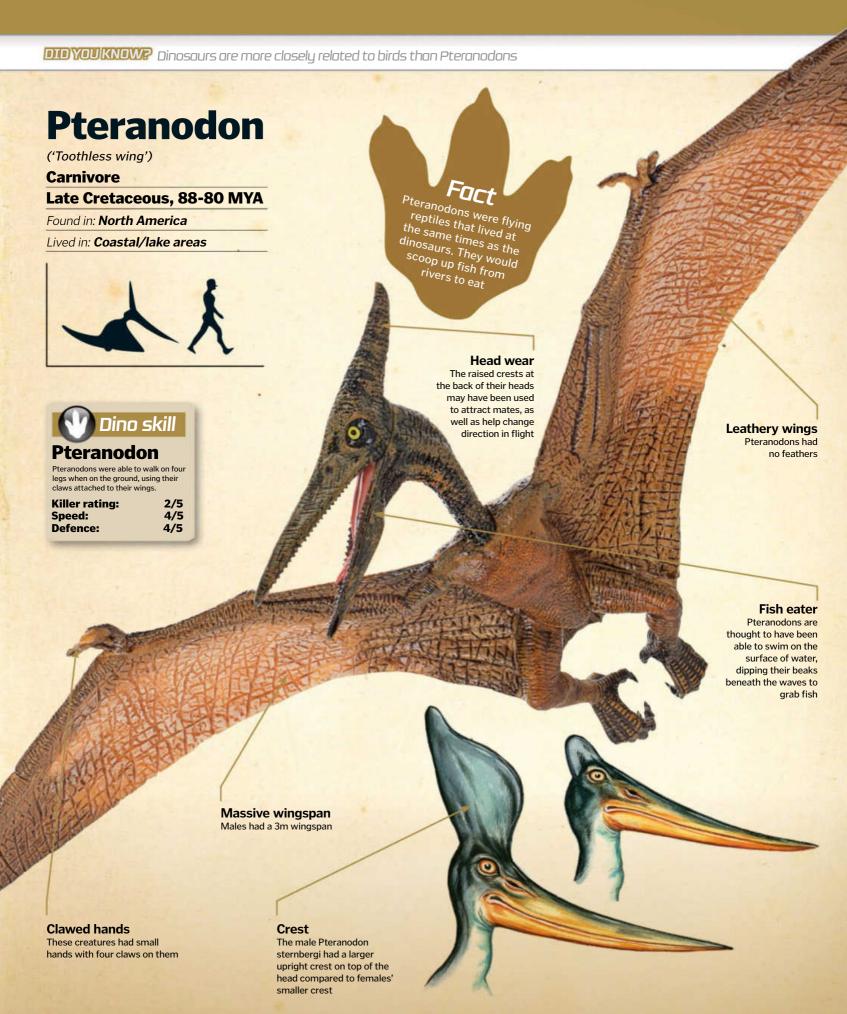

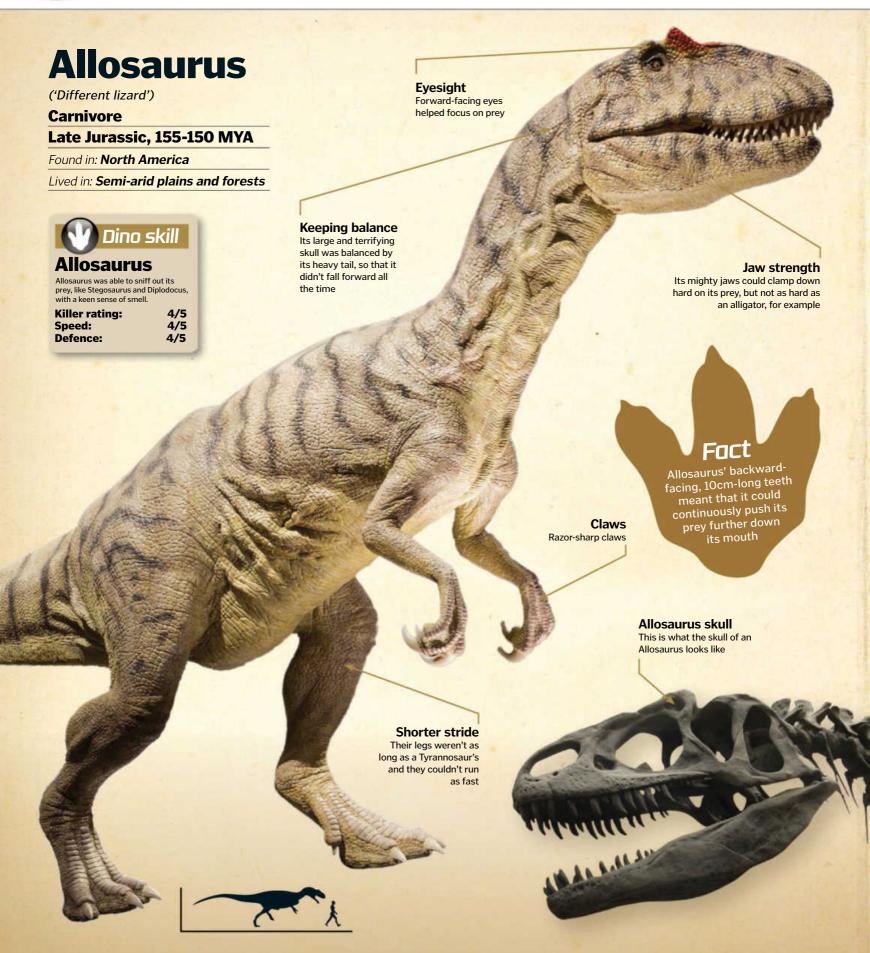

Vertebra

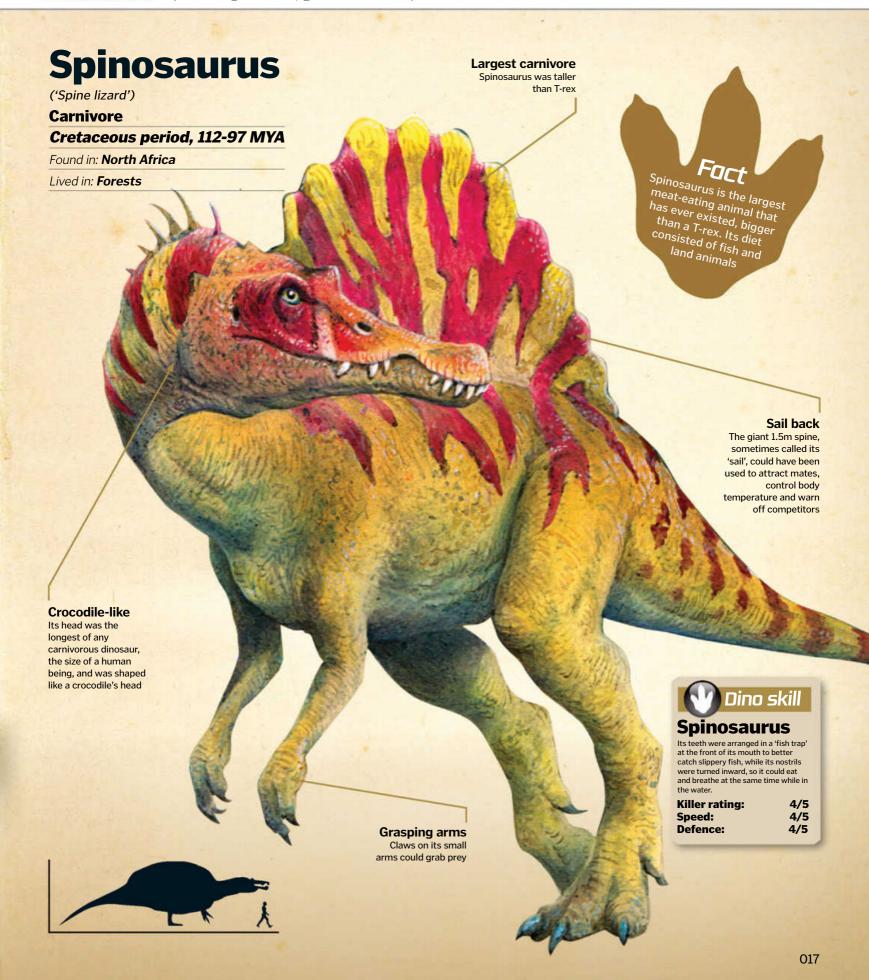

This is a bone from the long neck of the Brachiosaurus called a vertebra

their front legs were longer than their back legs, which provided additional elevation

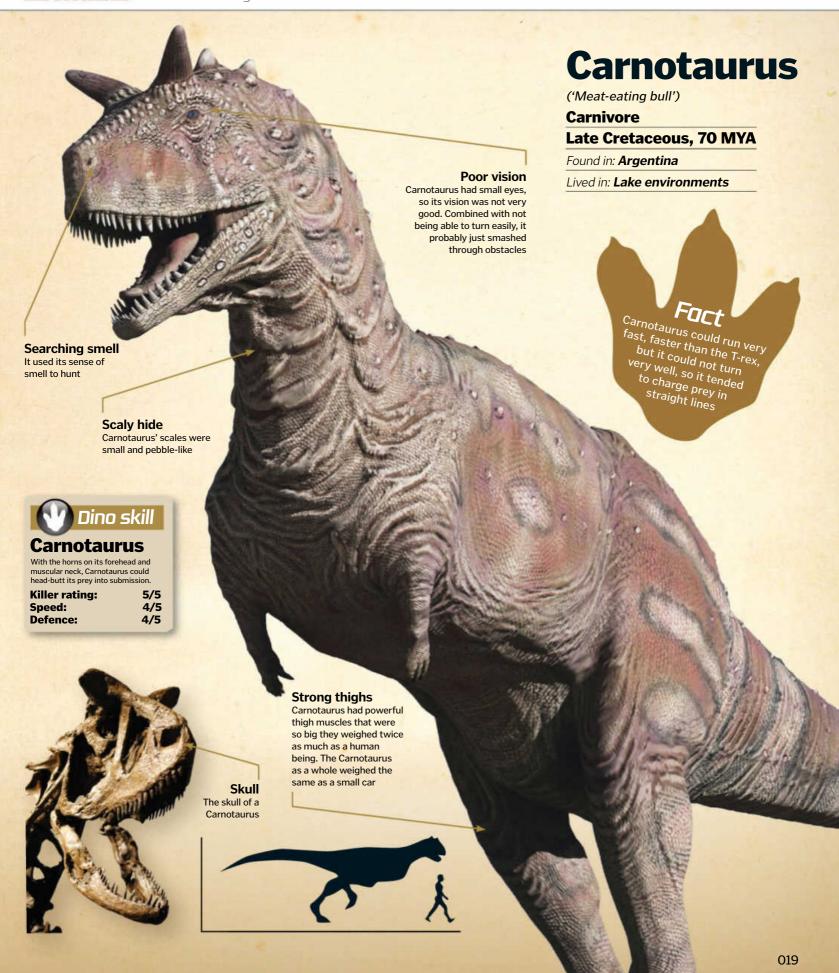

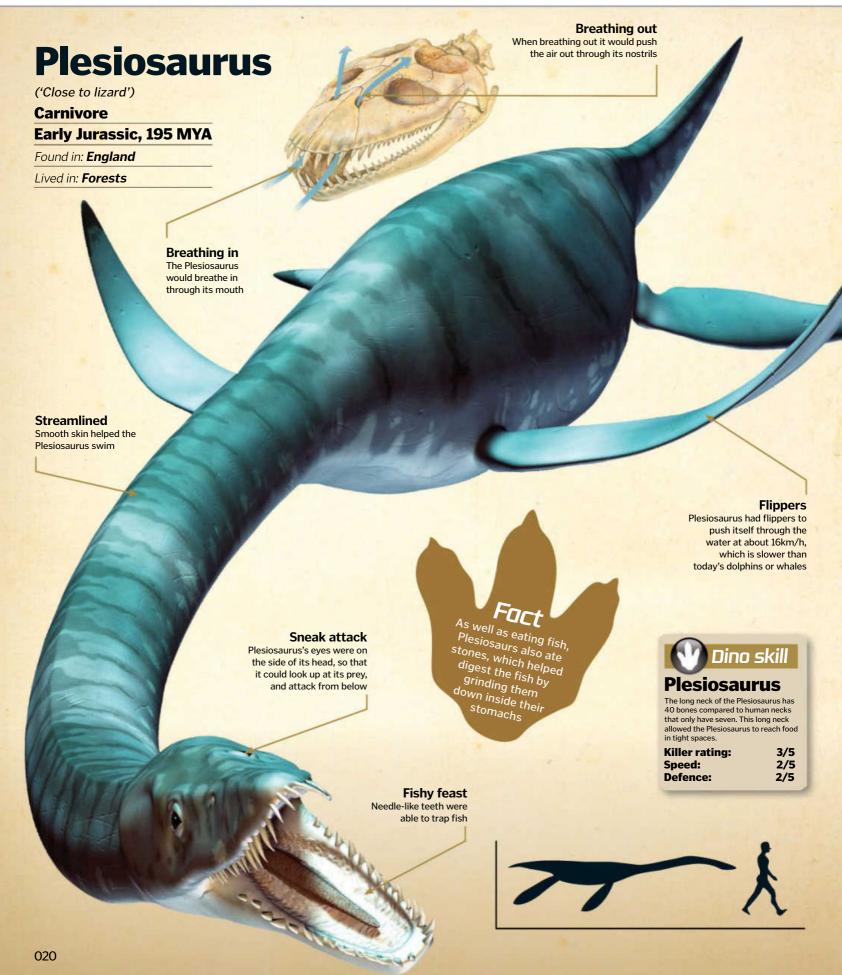

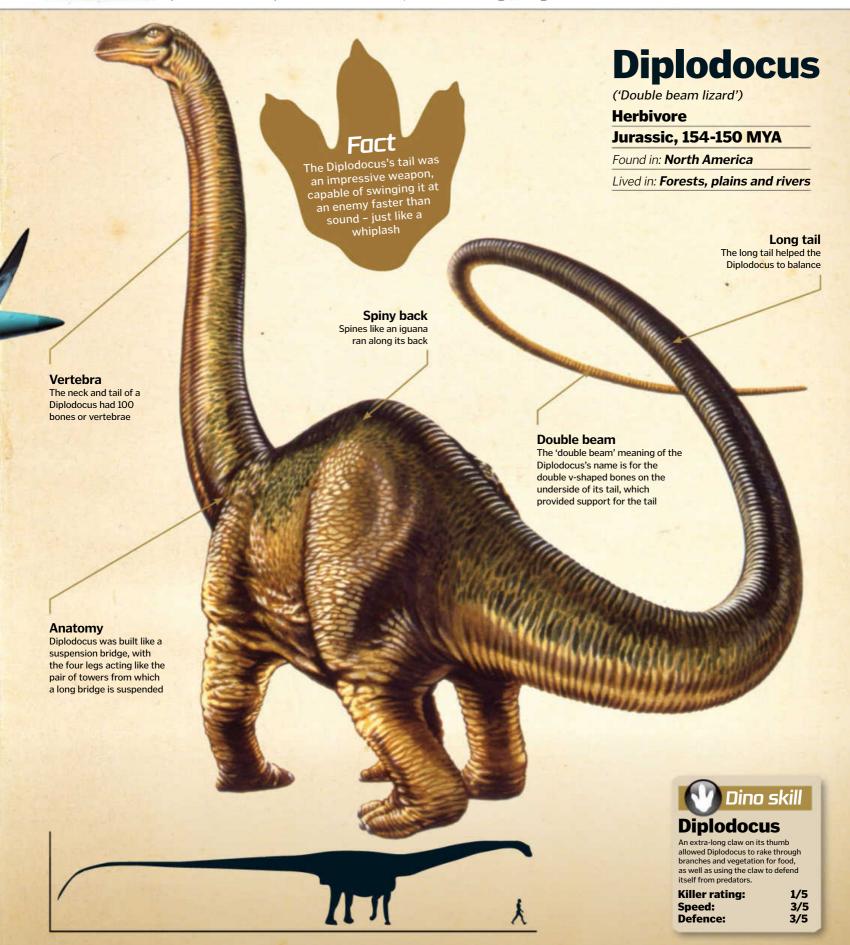

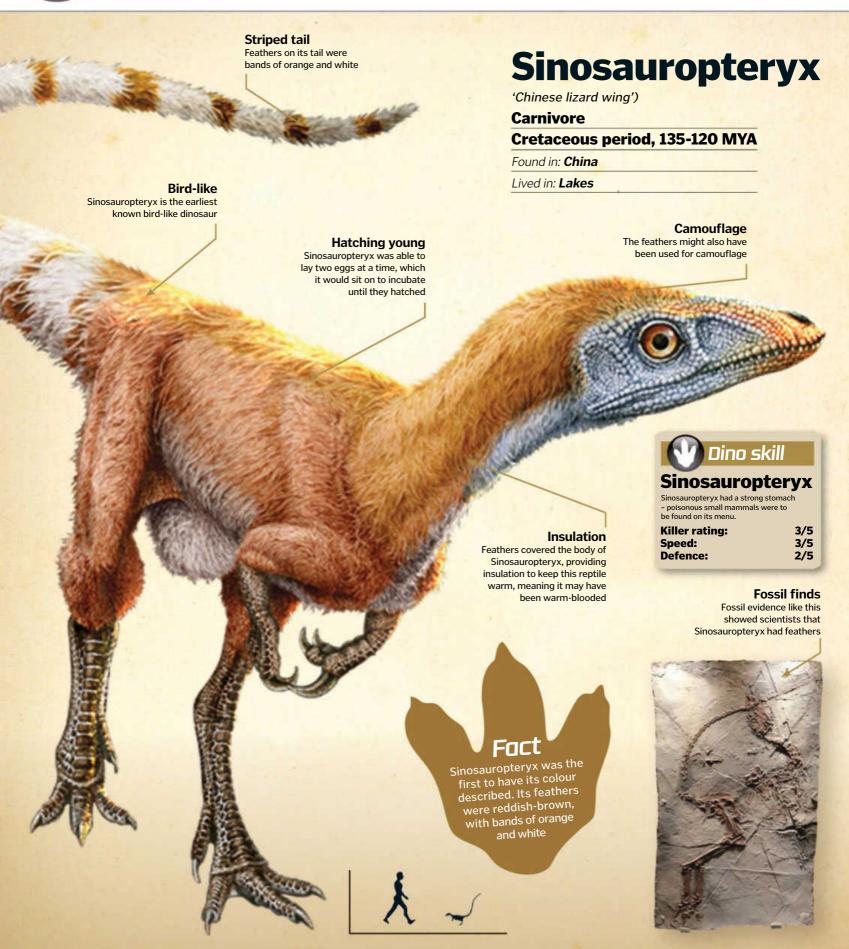

Ankylosaurus

('Fused lizard')

Herbivore

Cretaceous, 70-65 MYA

Found in: South America

Lived in: Coastal plains

Spiky defence

Two rows of spikes ran along its body, plus there were two large horns from the back of its head that it could defend itself with

Dino skill Ankylosaurus

Its club-like tail was a vicious weapon that the Ankylosaurus could use to defend itself from attack.

Killer rating: 3/5 Speed: 3/5 Defence: 5/5

Ankylosaurus was built like a tank and had strong plates of bone fused into the skin on its back that was impenetrable to even T-rex

Breaking bones

Powerful club-tail could break an attacker's bones

Early impression

This is an old sketch of an Ankylosaur's skeleton, before the tail club was discovered

Five-toed

Ankylosaurus probably had five toes on each foot

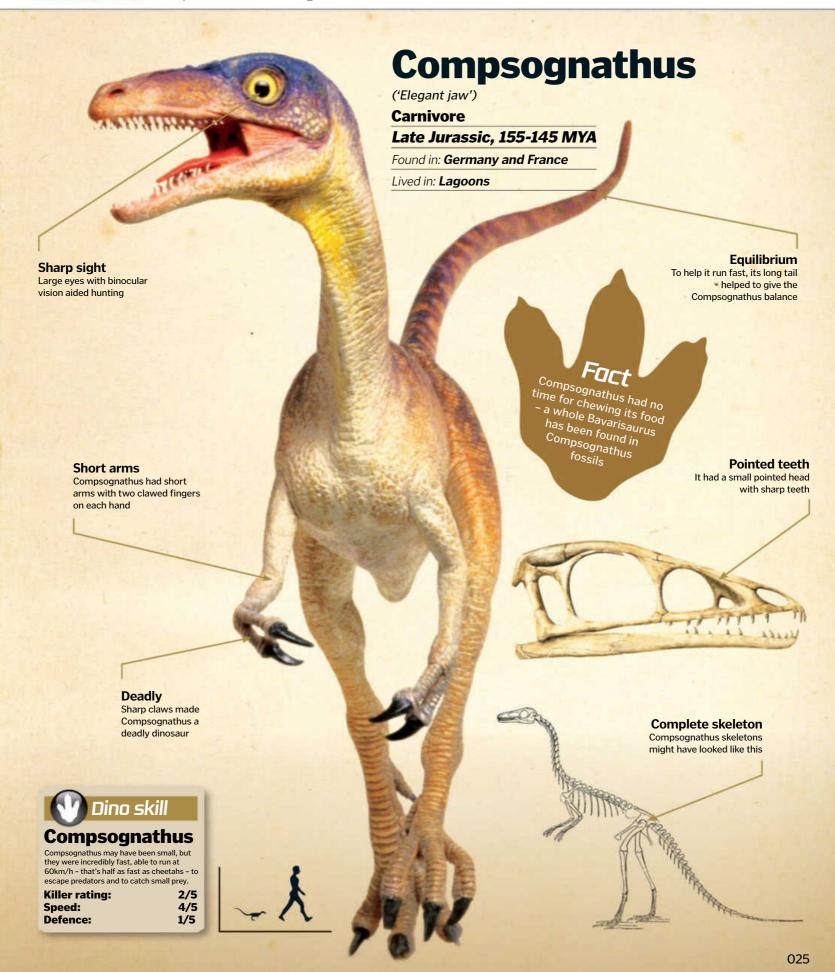

Vulnerable

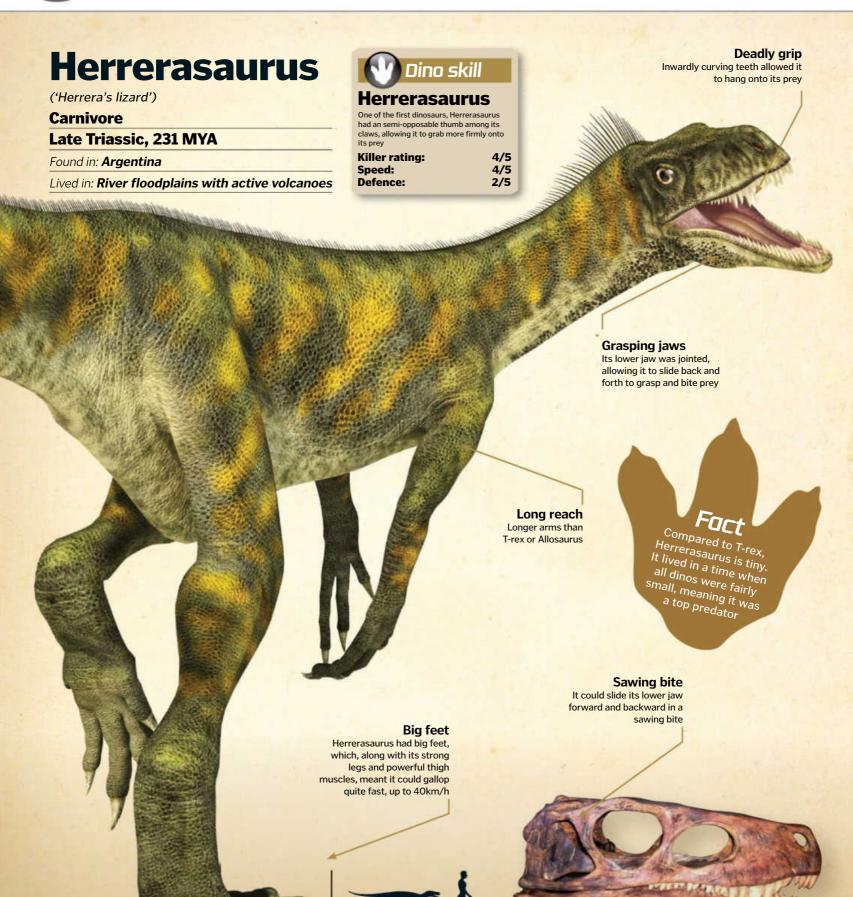

The underside of its belly was the only place the Ankylosaurus was not armoured - flipping it over was the only way to kill it

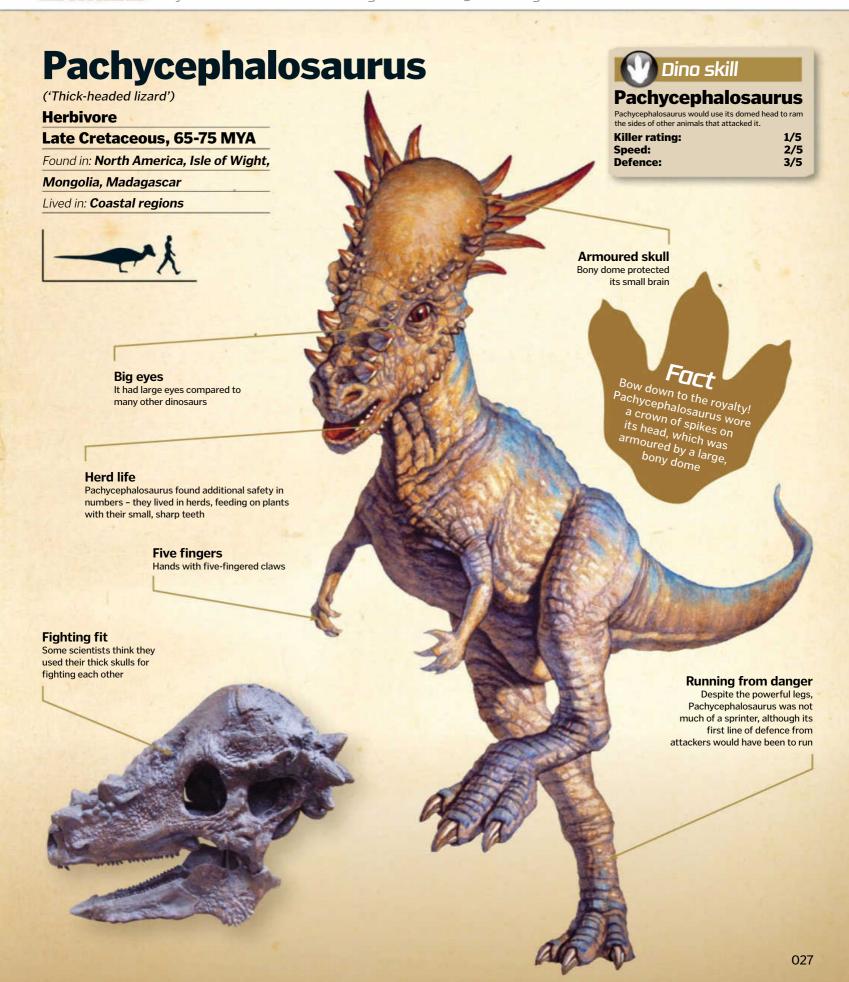

Bone head

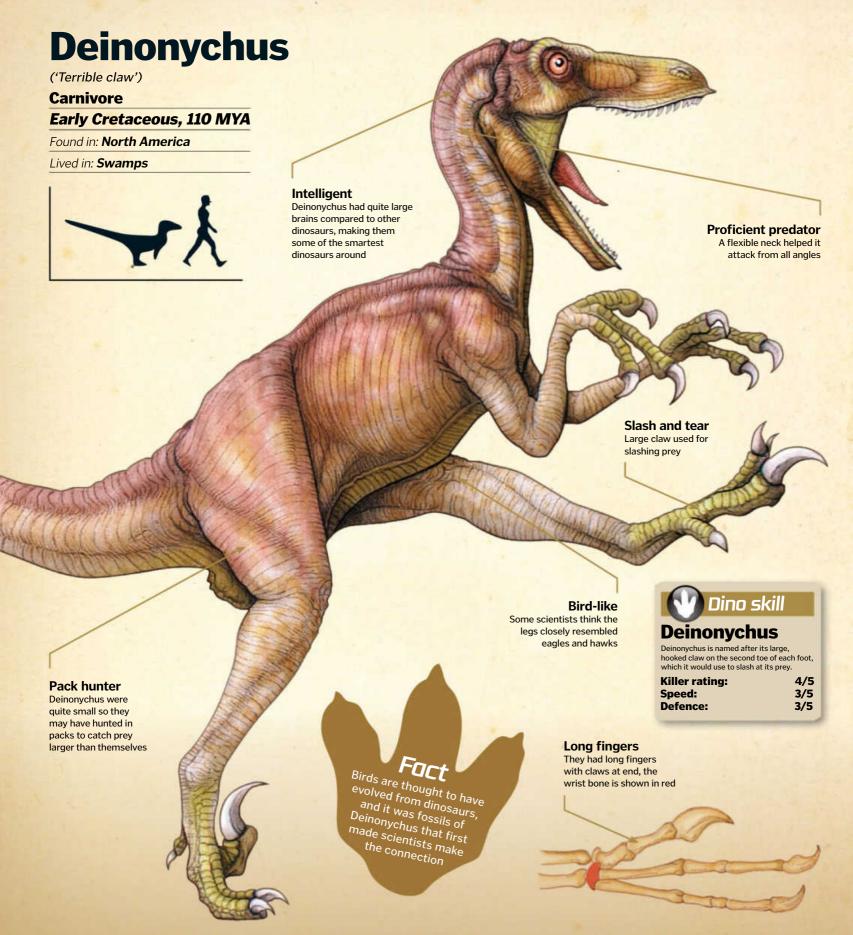

Its entire head was covered in bony plates

Liopleurodon

('Smooth-sided teeth')

Carnivore

Mid-Jurassic, 160-155 MYA

Found in: Europe

Lived in: The sea

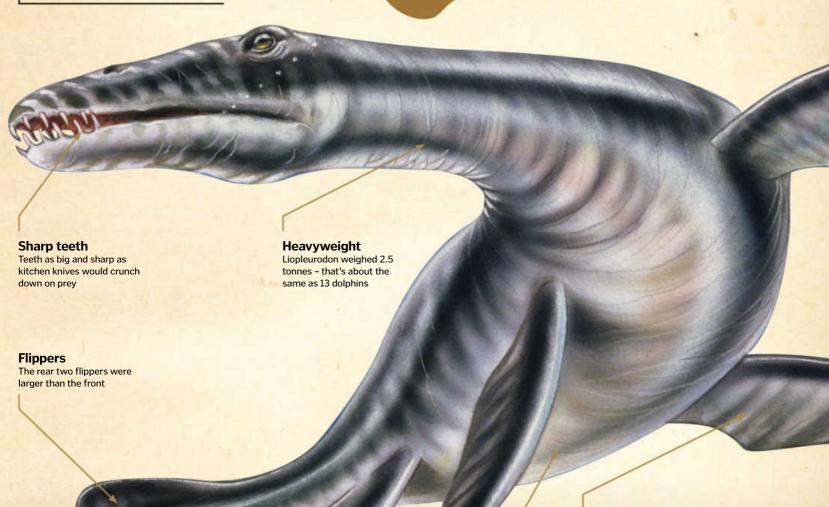

Liopleurodon

In the dark seas of the Jurassic era, the Liopleurodon used its keen sense of smell to sniff out prey that had the misfortune to swim past it.

Killer rating: 4/5 Speed: 3/5 Defence: 0/5

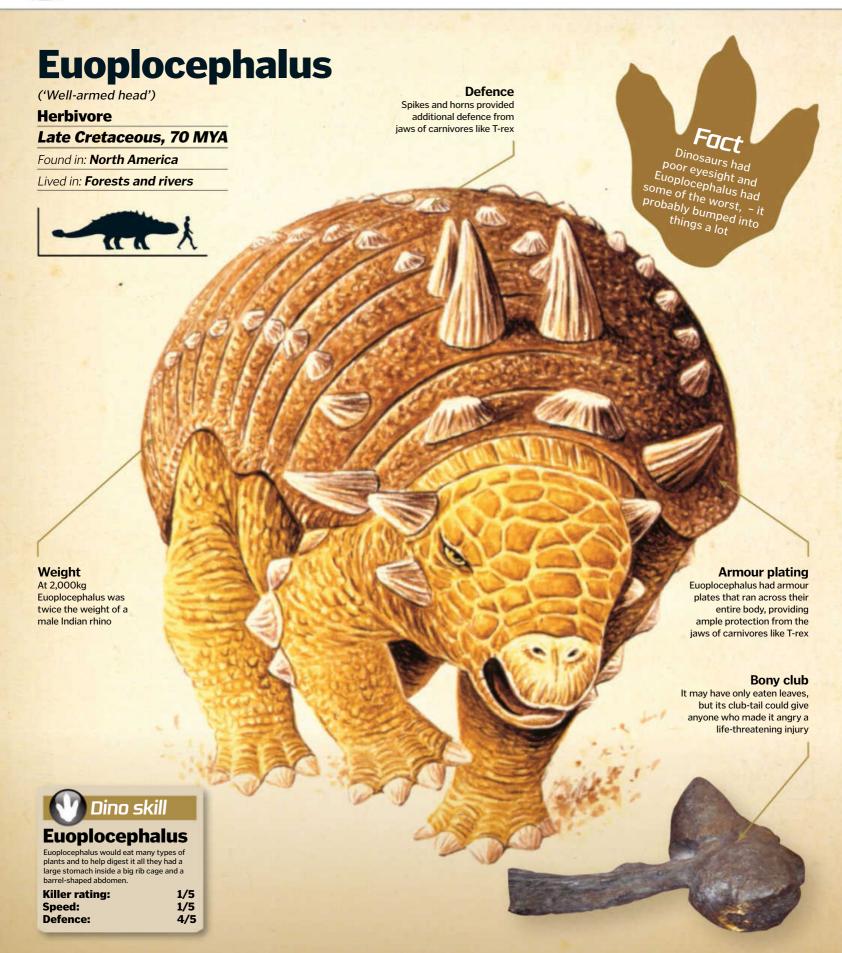

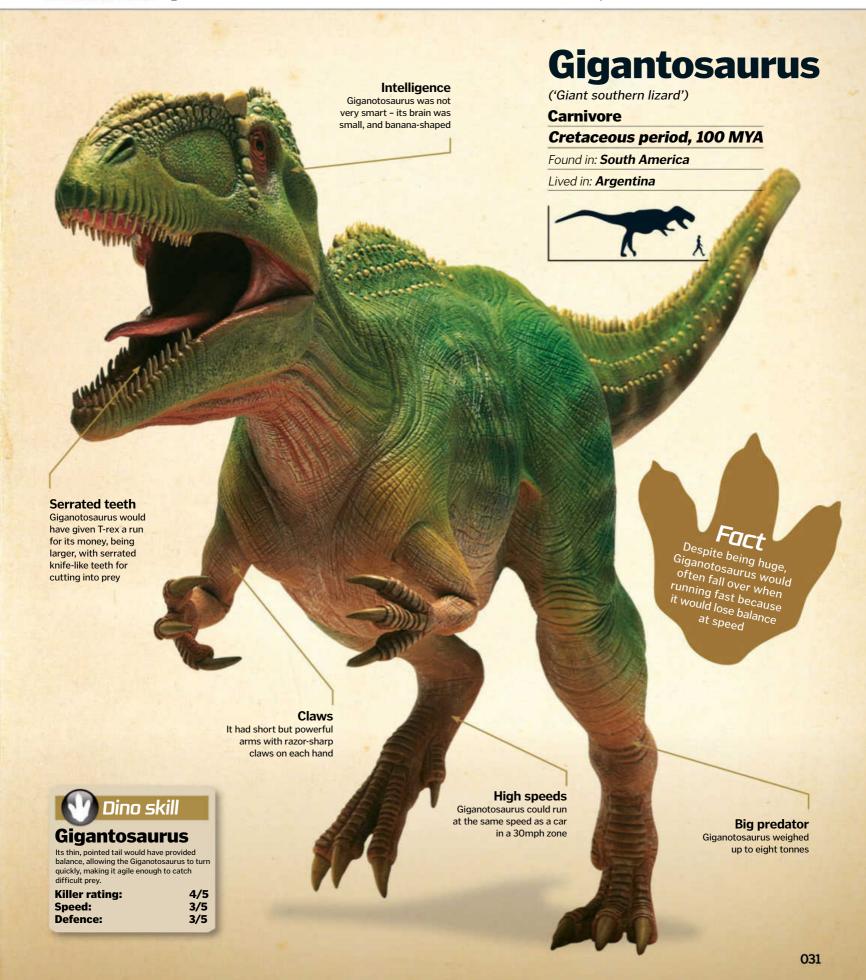

Speed

The Liopleurodon's four flippers propelled it through the water, but not very fast, swimming at only 10kmh

Super size

The Liopleurodon was longer than a sperm whale

Iguanodon

('Iguana-tooth')

Herbivore

Early Cretaceous, 130 MYA

Found in: Europe, North America,

Africa, Asia

Tail

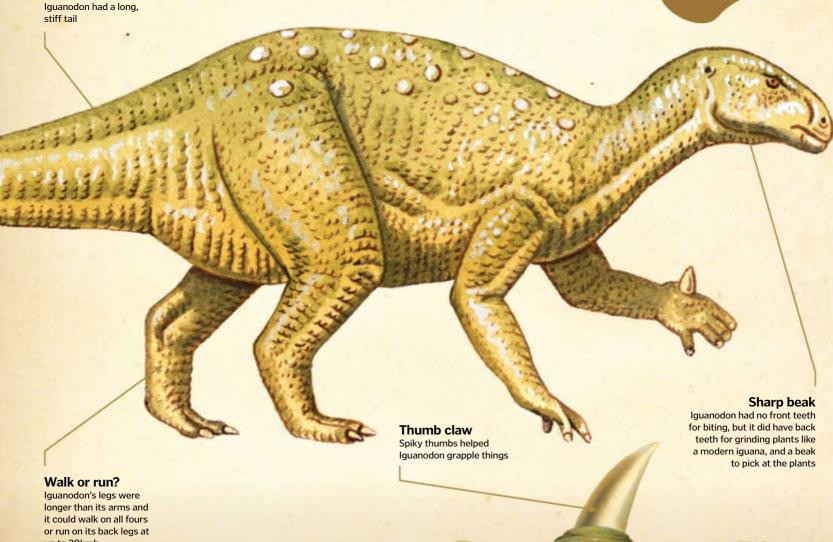

Lived in: Forests, plains and rivers

The Iguanodon's claws also had a thumb spike, which could have been used to help grab food, as well as fend off any attackers that got too close.

Killer rating: 3/5 2/5 Speed: **Defence:**

up to 20kmh

Seismosaurus

('Quake lizard')

Herbivore

Late Jurassic, 156-145 MYA

Found in: North America

Lived in: Forests, plains and rivers

Seismosaurus

Its long neck ended in a small head armed with peg-like teeth that could strip entire woodlands of their leaves and other foliage in no time at all!

Killer rating: 1/5 1/5 Speed: **Defence:** 4/5

Fact Seismosaurus is a giant version of the Diplodocus. The ground would literally have shaken when this beast lumbered past

Sturdy legs

Its enormous weight meant Seismosaurus needed very strong and sturdy legs to hold it up

Long reach

A long neck allowed Seismosaurus to reach food

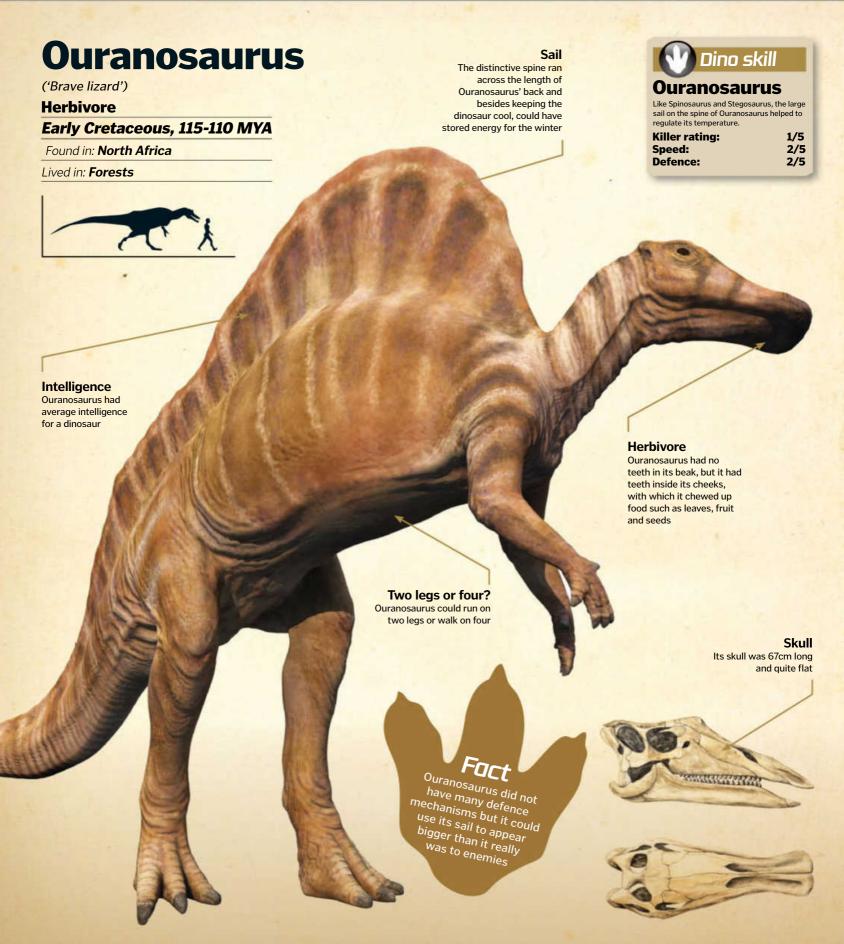

Herding instinct

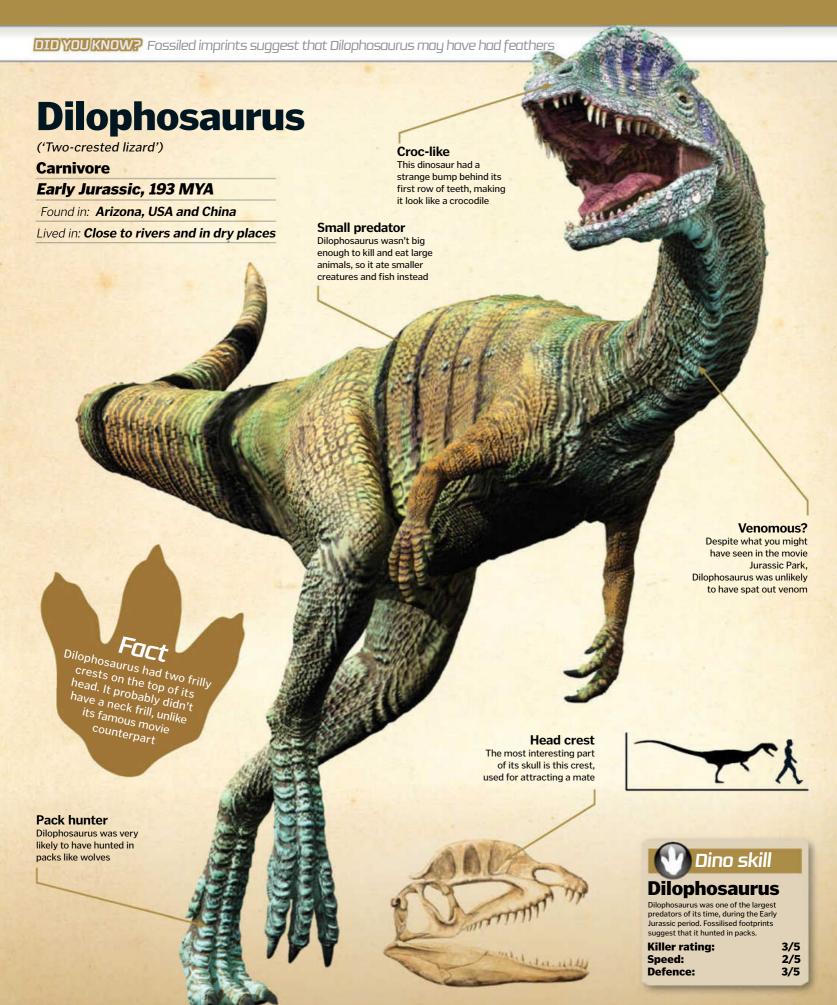

grazing herds

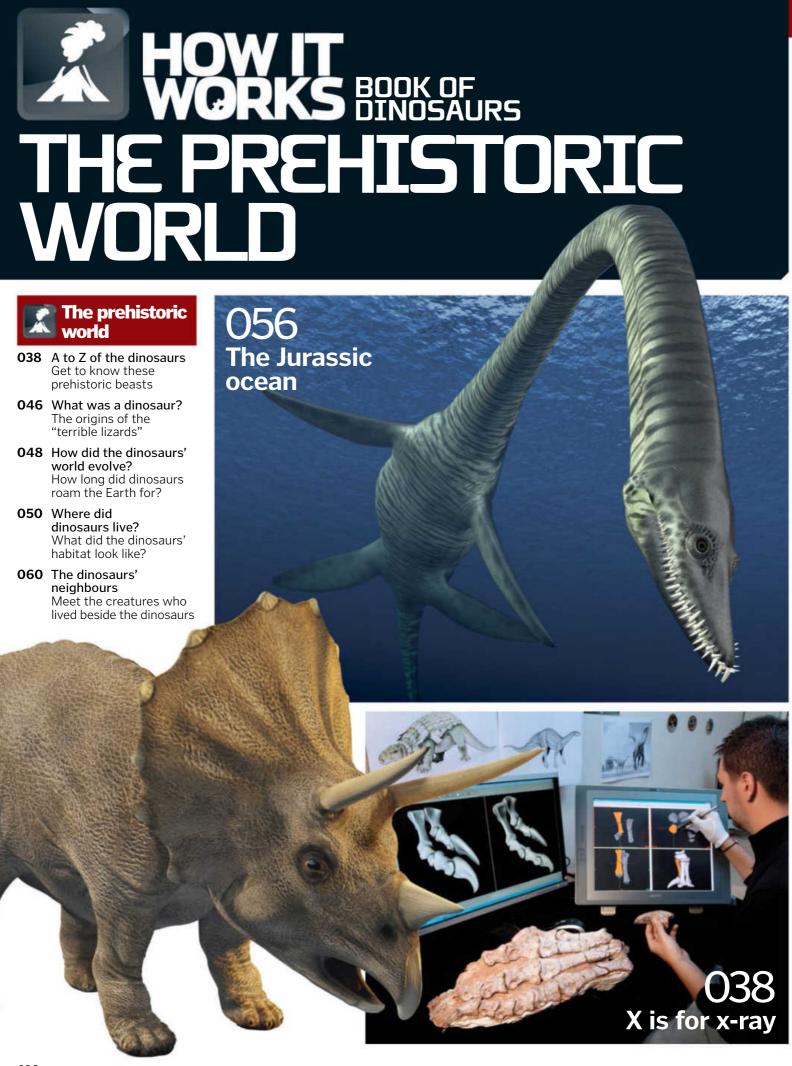

Seismosaurus travelled in

Whip-like tail Its long tail was a deadly weapon to be used against any would-be attackers

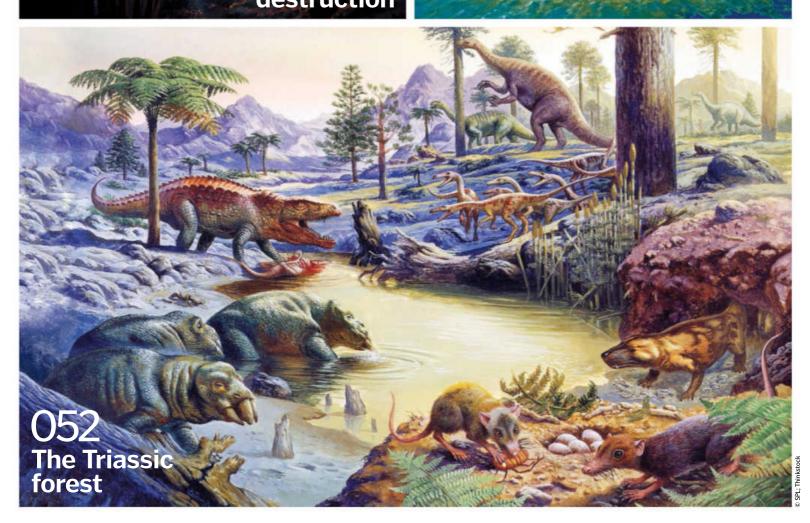

033

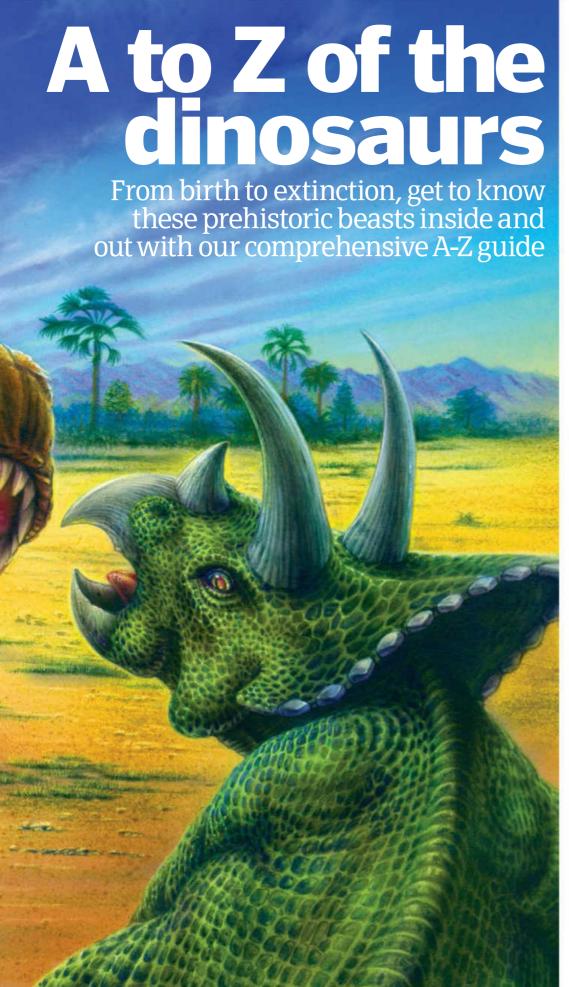

Dinosaurs have long sparked our imagination. From the Ancient Greeks' perception of their remains as

evidence of a time when giants ruled Earth, right through to modern man's pursuit of their resurrection – be that in films like *Jurassic Park* or in laboratories via advanced DNA cloning techniques – dinosaurs remain a tantalisingly alien part of our world's history.

They may no longer roam the land like they did millions of years ago, but thanks to their genetic legacy and preserved remains they still remain a very real presence today.

From the fossils lying trapped in the ground through to the descendants flying above our heads, dinosaurs have unique tales to tell.

We take a closer look at this ancient world through an A-Z encyclopedia of all things dinosaur. You'll learn not just about the creatures themselves but the tools and techniques used to study them, and what Earth was like during their reign. This guide truly has it all, so strap yourself in and prepare for one wild, prehistoric ride...

Professor Mike
Benton,
palaeontologist
Mike Benton is the
Professor of Vertebrate
Palaeontology at the
University of Bristol,
UK, and is a worldrenowned dinosaur

specialist. His areas of expertise include the diversification of life through time, the origin of dinosaurs and the end-Permian mass-extinction event. He can be found working on digs in Russia and China. He offers words of wisdom throughout our dino guide, but for a more in-depth interview, head to howitworksdaily.com.

É PREHISTORIC WORLD

A to Z of dinosaurs

Amber & dino DNA Amber is fossilised tree resin that, due to a chemical change after burial in the ground, turns into a solid. Despite its stable state today, when the majority of the Earth's amber formed, it was far more fluid, which means many little organisms unwittingly became stuck within it - including plant matter and insects. Today these appear frozen

within the amber and have been perfectly preserved. While one or two studies in the Nineties claimed to extract DNA from these organic inclusions (as portrayed in Jurassic Park), more recent research suggests this isn't possible. Scientists at the University of Manchester using advanced DNA sequencing in 2013 were not even able to find traces of DNA in copal (a precursor to amber) only 10,000 years old, so they're very doubtful that dino DNA could have survived from millions of years ago.

Communication in focus Dinosaurs, much like the many species of animal alive today, communicated in very different ways. From complex dance-like movements to more obvious calls and scent markings, each dino marked their territory, warned of potential predators and relayed information regarding food in its own unique way. One of the most

interesting examples comes in the form of the hadrosaurid (above), a duck-billed dinosaur family sporting a distinctive bone crest on their heads. These crests were used as a resonating chamber for projecting their calls. Considering the hadrosaur's modest size and its wide range of predators, the ability to amplify its calls was no doubt a valuable defensive mechanism.

Bone secrets

Dinosaur bones are one of a palaeontologist's greatest sources of information, supplying data about their age, anatomy, distribution and much more. The bones of dinosaurs can only be found if they went through the process of fossilisation, where the tissue of the creature dissolves and gets replaced with minerals under pressure beneath the ground. Finding and extracting these fossilised bones is a major challenge for palaeontologists, with a carefully planned out dig site essential.

"Certain kinds of excavation and study out in

the field can be for palaeoecology, trying to reconstruct food webs and modes of locomotion, or they can be about looking at patterns over time, going up metre by metre in rock formations and analysing fossil groups to see how they change" Most fossils are discovered at first only in part, with just a small fragment visible above the surface

Discovery

Shooting in situ

Photography plays a crucial part of any excavation. The specimen is continuously snapped from its discovery right through to removal

Clearance

Once the fossilised bone has been photographed, the rock around it is carefully cleared to allow better access to the fossils

When the fossil is freed from the rock, a painstaking process of cleaning follows

delicate the tools

Tools

Boundary As soon as the fossil has been confirmed, a boundary is staked, protecting the area so palaeontologists can work unhindered

Clearance is achieved with chisels, hammers

and spades. The closer

to the fossil the more

Extraction

The fossil is cut from the surrounding rock and removed piece by piece, with each one meticulously labelled

Packed up

The fragile specimens need to be transported with great care, with fossils placed in padded containers

Analysis

At the research lab, the fossil can be studied in depth, with laser scanning revealing in-depth detail about the dinosaur DIDYOUKNOW? You can see a Diplodocus skeleton in the Natural History Museum, UK

Diplodocus: a dino titan

Of all the dinosaurs that lived on Earth few can truly lay claim to be a terrestrial giant - but the Diplodocus can. Built like a suspension bridge, the Diplodocus measured over 25 metres (82 feet) long that's longer than five African elephants! It weighed over 12 tons, roughly 170 times more than the average human. It had an

incredibly long neck and counterweight tail, the former used to elevate its head into the foliage of trees for food, while the latter was its primary form of defence. With a typical Diplodocus estimated to have lived between 50 and 80 years, it also had one of the longest life spans of any dinosaur from the Jurassic period.

to rely on a fair number of fossil feathers that were exceptionally well preserved and deep within their internal structure we could see colour-bearing organelles. So by using some smart observations and techniques we have proved it to be possible"

answers to. But we were able

Extinction

Dinosaurs perished some 65 million vears ago in what is known as the K-Pg (formerly K-T) extinction event. This cataclysmic event at the Cretaceous-Palaeogene boundary led to 75 per cent of all species on Earth dying off. From the smallest ocean plankton to the largest land beasts, the K-Pg extinction event resulted in devastation at every level of the world's ecosystems, with all non-avian dinosaurs eradicated. The current theory for the catalyst of this global wipeout is an asteroid impact in South America, but the real cause for such widespread carnage was not the impact itself but its knock-on effects. These include plants not being able to photosynthesise due to dust blocking out the Sun plus a series of epic tsunamis and fire storm

Feathered fiends

Since palaeontologists began uncovering dinosaur remains in the 19th century, our depictions of them in the flesh have been largely coloured by a few initial artist impressions, with figures such as Charles Knight often drawing species in inaccurate postures and with factually incorrect sizes, colours and features. Based on current evidence, the lack of feathers on most species is one of the most obvious flaws in these early depictions, with half of all non-avian theropods now thought to have been partly feathered. The main cause for these misassumptions has been the lack of evidence, with feathers and soft tissues rarely preserved like fossilised bone.

Genetic legacy

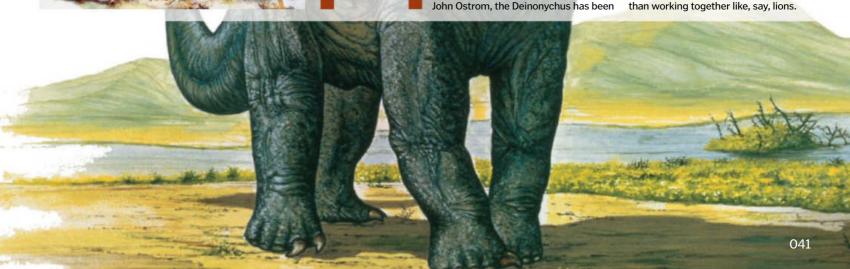

Today the study of dinosaurs is entering an exciting new age, where we can achieve an unprecedented level of accuracy through cutting-edge analysis. After a T-rex's soft tissue was discovered within a bone sample, we can now study things like proteins, blood vessels and other micro-anatomy to help us determine how individuals lived and died, as well as how dinos evolved.

Hunting strategies

Whether dinos hunted and scavenged alone like the T-rex or in large packs like the Deinonychus - the model for the Velociraptor in Jurassic Park carnivorous dinosaurs were no doubt the apex predators on Earth. However, debate rages as to how co-ordinated dinosaur pack hunters were. Since first described in 1969 by palaeontologist

imprinted in the public consciousness as a highly intelligent, synchronised team hunter. However, many modern dino experts disagree with this assumption, believing that while Deinonychus did move and chase prey in groups, they did so with little co-ordination, with each individual simply acting out of self-interest rather

WORKS THE PREHISTORIC WORLD

A to Z of dinosaurs

Ichthyosaurus

Although technically not a true 'dinosaur', Ichthyosaurus, or 'fish lizard', filled the same niche in Farth's oceans and was one of the most dominant marine species of the Mesozoic era (252-65.5 Ma) Resembling today's dolphins, Ichthyosaurus measured in at roughly two metres (6.6 feet) in length and was capable of cruising through the water at around 40 kilometres (25 miles) per hour, enabling it to catch fish and squid with ease. The fact that Ichthyosaurus had a verv large pair of eyes protected by a pair of bony, structuralsupporting rings has led some palaeontologists to believe the species frequently hunted at great depths where pressure was very high

Eves

Large eyes were protected by rings of bone to keep them intact at great depths.

Teeth

The jaws were lined with rows of sharp, conical teeth, primed for shredding soft prey such as squid.

Fins

Stunted limb-like fins were used for stability and manoeuvring rather than propulsion.

Prey

Fish, squid and marine reptiles were the main food of Ichthyosaurus, but the sharp teeth could crush shellfish as well.

Body

Its body was streamlined, with a curved spine and no neck. By undulating its body it could alter its speed and direction.

6 Tail

A top speed of 40km/h (25mph) came courtesy of the bilobed, shark-like tail.

Jurassic lark Five factual bloopers from the famous Hollywood films

Timing problems
Jurassic Park portrayed
many famous dinosaur
species, including T-rex
and Triceratops, but
most of the animals
shown actually lived in
the Cretaceous period,
not the Jurassic.

Out of proportion

One thing the film's producers definitely need punishing for is the depiction of the park's Velociraptors. Portrayed as being as tall as a man, in reality they barely stood 0.5m (1.6ft) off the ground.

Feather-brained Another massive

omission in Jurassic Park was the lack of any feathers. Most dinosaur species, especially sauropods, had some plumage on their bodies.

No grudge match In the third film, the

Spinosaurus is shown going toe-to-toe with its supposed arch-nemesis, the T-rex. In reality they never met as they lived on different continents of prehistoric Earth.

Spit on a grave

Another creative addition was Dilophosaurus's ability to spit out venom. However there is no evidence to suggest it could do this; neither did it have a frilled neck.

King of the dinosaurs

While not the biggest or smartest, the Tyrannosaurus rex was no doubt the closest to a king the dinosaurs ever had. A colossal bipedal carnivore, the T-rex measured in at over four metres (13 feet) tall and over 12 metres (39 feet) long, weighing over seven tons. It was no slow-poke either, with computer models estimating that the dino was capable of hitting a top speed of around 29 kilometres (18 miles) per hour chasing prey. When it caught up it could quickly dispatch them with a single bite that had a force of three tonnes – the equivalent weight of a fully grown African elephant. Yikes!

Skul

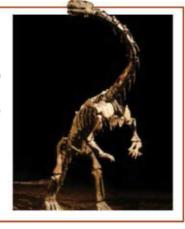

A heavy skull was adapted to withstand biting and shearing forces, with particularly strong nasal bones

Lungs

Evidence of honeycomb structures within its vertebrae suggest that T-rex breathed through a complex system of pockets and air sacs

Lufeng: a fossil treasure trove

One of the most prolific dinosaur hotspots in the world is Lufeng in Yunnan Province, China. Since 1938, 33 species, each with its own complete fossil, have been found there. Some of the finds have been record-breaking, with many of the vertebrate fossils uncovered the oldest on record – the Lufengosaurus fossil (right) dates from 190 million years ago. Lufengosaurus was a genus of prosauropod that lived during the Early Jurassic period. Excavated finds can be seen at the Lufeng Dinosaur Museum.

Forelimbs

The T-rex's front limbs were short and stocky, with each exhibiting a thick cortical bone. They were used to hold on to struggling prey

Heart

With a body bigger than a bus, the T-rex needed a huge pump to transport blood at adequate pressure. Current estimates suggest its heart was over 100 times bigger than a human's

Stomach

The T-rex had a hardy stomach due to its high-meat diet and the fact that it scavenged frequently from long-dead carcasses. Analysed T-rex dung has revealed many fragments of bone

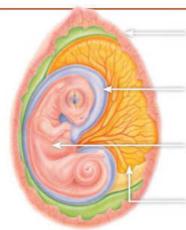

Mesozoic world

Beginning 252.2 million years ago and coming to a close about 65 million years ago, encompassing a colossal stretch of time that includes the Triassic. Jurassic and Cretaceous periods, the Mesozoic era truly defined the age of dinosaurs. All the famous species you can think of lived within it.

The Mesozoic was generally warm with a significantly smaller temperature differential between the equatorial and polar regions - ideal conditions for the emergence and proliferation of flora and fauna. Not only was the Mesozoic famous for its domination by dinosaurs, but also for being the time period where the ancestors of today's major plant and animal groups emerged.

Nesting & dinosaur eggs

Dinos organised their nests, laying their eggs in patterns suggesting complex social behaviours. Palaeontologists have identified two main types of egg-laying strategies clutches and linear patterns - further divided by the shape of the nest and distribution of eggs. For example, the ornithopod Maiasaura nests generally consisted of bowl-shaped excavations roughly two metres (6.6 feet) wide and 0.8 metres (2.6 feet) deep, the opening covered by loose vegetation, Each nest was spaced roughly seven metres (22 feet) apart and was used by their offspring until they were over a metre (3.3 feet) long.

Outer shell

Dinosaur eggs were elongated and had hard, brittle shells. Some of the largest found to date were 0.6m (2ft) long

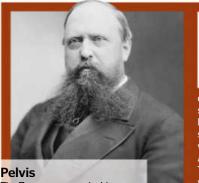

Amniotic membrane

Encompassing the dinosaur was a thin membrane, helping keep the embryo hydrated during development

Embryo

At the centre lay the dinosaur embryo that, depending on the species, could take weeks or months to hatch

This contained proteins and fat which served as food for the baby dino

The T-rex was a saurischian dinosaur, meaning it had a lizard hip arrangement. Its pubis bone pointed forward and down rather than backward and down like ornithischian species

Palaeontology: key players

Most of our current knowledge of the dinosaur kingdom comes courtesy of palaeontologists, who dedicate their lives to uncovering the secrets of their prehistoric kingdom. From the earliest dinosaur hunters such as Othniel Marsh (pictured left), who discovered and named the Allosaurus, Stegosaurus and Triceratops, to 20th-century scientists who revolutionised our understanding

of the dinosaurs' legacy, such as John Ostrom who gained fame for his suggestion that birds were modernday descendants, palaeontologists have helped provide tantalising glimpses of the prehistoric world.

One of the more contemporary palaeontologists who has helped introduce dinosaurs to the general public is Dr Philip J Currie. He is also a museum curator who helped found the prestigious Royal Tyrrell Museum of Palaeontology in Alberta, Canada.

Body

Unlike popular depictions, it did not stand vertical on its large hind legs but leaned forward with its body approximately parallel to the ground

"Weighing something like five tons yet walking bipedally makes the T-rex incredibly interesting, as it pushes the absolute limits of what is possible. I mean, you look at an elephant and think, 'Wow, that's amazing',

however, an elephant has to walk on four legs and weighs roughly the same amount, so understanding how T-rex functioned is a fascinating area of research"

Tail

A muscular tail helped counterbalance the T-rex's heavy skull and aided locomotion, improving leg retraction speeds

Queensland

If you were to visit Queensland's more remote regions, you may very well find yourself standing face to face with one of many 100-million-year-old beasts. That's because Oueensland's outback was once part of the Great Inland Sea, a huge swampy inland ocean that existed in the age of the dinosaurs. As such, hundreds of fossils have been excavated from this region and there is even an established 'Australian Dinosaur Trail' that tourists can follow.

Oceans & continents

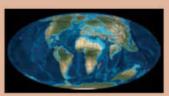

Triassic At the beginning of the Mesozoic era in the Early Triassic period, all the land on Earth was joined together into the supercontinent of Pangaea, itself surrounded by the superocean Panthalassa.

2 JurassicAs the Mesozoic progressed and the Triassic made way for the Jurassic period, plate tectonics split Pangaea into two mega-continents: Gondwana and Laurasia, separated by the Tethys Sea.

3 CretaceousAs the Mesozoic came to a close, Gondwana and Laurasia had split into many of the continents we know today, including North and South America and Antarctica.

Palaeogene In the Palaeogene period - immediately following the K-Pg extinction - those continents continued to move to their current positions.

Hind legs

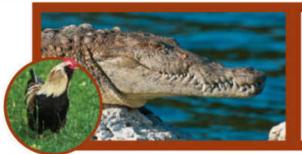

it to hit around 29km/h (18mph). It was probably poor at turning though

THE PREHISTORIC WORLD

A to Z of dinosaurs

R

Relatives in the modern world

Massive scientific effort has been put into identifying which creatures today can trace their roots back to these prehistoric beasts. One of the best examples of this was the hunt for the nearest living relative of the once-mighty T-rex, undertaken by a research team at the North Carolina State University in 2007. To go about this the researchers

sequenced proteins from a 68-millionyear-old T-rex tissue sample and, much to their surprise, discovered that the king of the dinosaurs' molecules showed remarkable similarity to the common chicken and that its collagen makeup was almost identical. So, at least for the time being, the humble chicken is the rightful ruler of the Earth...

Plates

Two rows of triangular back plates are believed to have acted as key components of a thermoregulatory system, serving as organic radiators

Skull

The skull was relatively small, slender and low to the ground, helping it graze on low-growing plants and vegetation

Stegosaurus
One of the most recognisable
dinosaurs of all time, the
Stegosaurus – despite its herbivorous
nature – was a formidable opponent,
with its large muscular tail tipped
with lethal bone spikes. With a
length of about nine metres (30
feet) and a typical weight of two
to three tonnes, the Stegosaurus
had a rounded body and heavy skull.
Stegosaurus lived in the Late Jurassic
period around 150 MYA.

Body

Due to Stegosaurus being vegetarian, it had a large stomach perfectly adapted to breaking down tough plant matter

Legs

The front limbs were far shorter than the hind limbs, granting its characteristically arched appearance

Tail

The powerful tail was tipped with bone spikes and could be swung at speed as a form of self-defence

Tall tails

You'll struggle to find a dinosaur without a tail. This is because the majority of dinosaurs used their tails for two important roles: the first being balance and the second being self-defence. Large animals like the T-rex and Diplodocus, thanks to their skulls or necks, were very top-heavy. They needed long and heavy tails to counterbalance this,

their skulls or necks, were very top-heavy.
They needed long and heavy tails to counterbalance this, especially when running. Smaller creatures such as Ankylosaurus (left) used its tail when under attack, evolving a large bony club at the end which could bludgeon assailants.

Unenlagia: half bird, half dinosau

One of the most telling links between dinosaurs and birds is the Unenlagia, a genus of theropod dinosaur from the Late Cretaceous that in almost all aspects, aside from flight, resembles a modern bird. It was discovered in 1997 and to date two species have been confirmed – U comahuensis and U paynemili – both of which share an almost identical pelvic structure to the early bird species Archaeopteryx.

Velociraptors debunked

Due to their appearance in the Jurassic Park films, the Velociraptor is easily one of the most recognisable of all species. Importantly though, this image of the Velociraptor is way off the mark in terms of reality.

In contrast to the movie monster, research evidence suggests that the Velociraptor was actually a feathered dinosaur under 0.6 metres (two feet) in length, with colourful plumage used in mating rituals and visual displays. The species also had hollow bones, much like birds, and built large nests to protect their offspring.

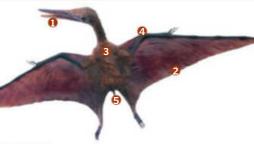

The Velociraptor did impress in ground speed, with it capable of hitting 39 kilometres (24 miles) per hour at top speed and boasting amazing agility, being able to change direction incredibly quickly. It used this speed to chase down prey, which largely consisted of small to medium-sized herbivores such as Protoceratops, and then kill them with its nine-centimetre (3.5-inch) retractable claws and sharp teeth.

New research suggests that, while sociable compared with other carnivores, raptors were not apex pack hunters, with co-operative kills possible but infrequent.

Winged wonders
While not technically dinosaurs,
pterosaurs were very much the winged
wonders of the dinosaur era. Flying reptiles that
evolved throughout the Late Triassic and dominated
the skies until the Late Cretaceous, pterosaurs
were the earliest vertebrates currently known

the skies until the Late Cretaceous, pterosaurs were the earliest vertebrates currently known to have evolved powered flight. Pterosaurs are not related to modern-day birds or bats, with the many species evolving earlier and separately. The genus Pterodactylus was one of the most

The genus Pterodactylus was one of the most notable, with the species Pterodactylus antiquus one of the most impressive, with a toothed beak, large eyes and clawed wings. In terms of wingspan P antiquus could extend its wings up to a metre (3.3 feet) and had a long, narrow skull packed with dozens of sharp, pointed teeth. It used these to snap up fish and smaller reptiles.

6

"Microraptor was a small, fourwinged dinosaur... very close to the origin of birds. Its remains show it had wings on its arms and legs. It couldn't fly properly,

but used its wings to glide. This shows the origin of flight in birds and their ancestors was much more complex than expected"

Beak

Up to 90 teeth in the long beak intermeshed when the jaw was closed, and were perfect for grabbing fast prey.

Wings

A wingspan of around 1m (3.3ft) was typical for Pterodactylus, with the wings structured in a way that indicates it would have flown like an albatross.

8 Body

Not as large as depicted in fiction, Pterodactylus was very lightly built with hollow bones and a long neck.

@ Limbs

Pterosaurs evolved a unique pteroid bone on the wrists of their forearms, used to support the forward wing membrane located between the wrist and shoulder.

6 Tail

Unlike some other pterosaurs, Pterodactylus had a relatively short, stubby tail.

X

X-raying prehistoric remains

X-ray scanners have become incredibly useful and important tools in the world of palaeontology as they can reveal many fossils and features that otherwise would remain hidden. For example, in November 2013, researchers in Germany used an X-ray machine to unveil the detailed structure of a fossil trapped within a plaster cast, all without ever

having to break it open and risking damage to the specimen. What's more, the researchers then made use of a 3D printer to re-create the X-ray scans in solid form, allowing palaeontologists to pick up and handle a cast of the fossil as fine and detailed as the real thing. Modern technology is set to further our understanding of dinosaurs by no bounds.

Yucatán impact

The colossal Chicxulub crater in the Yucatán Peninsula, Mexico, since its discovery in the Seventies, has heavily hinted as to how 75 per cent of all life on Earth was eradicated around 65.5 million years ago. The crater indicates that a space rock - iid - at least ten kilometres (six miles) arth As a result of the extensive

probably an asteroid – at least ten kilometres (six miles) across impacted Earth. As a result of the extensive damage caused directly by the collision and consequently by tsunamis, dust storms and volcanism, it caused a total collapse in the world's ecosystems, with all non-avian dinosaurs at the top of the death list. Despite being challenged repeatedly, the impact's link to the K-Pg mass extinction has recently been reaffirmed with even more detail, with a research team linking the two events in time to within 11,000 years. That said, the researchers also highlighted that various precursory phenomena, such as dramatic climate swings, also contributed to the end of the dinosaurs post-impact.

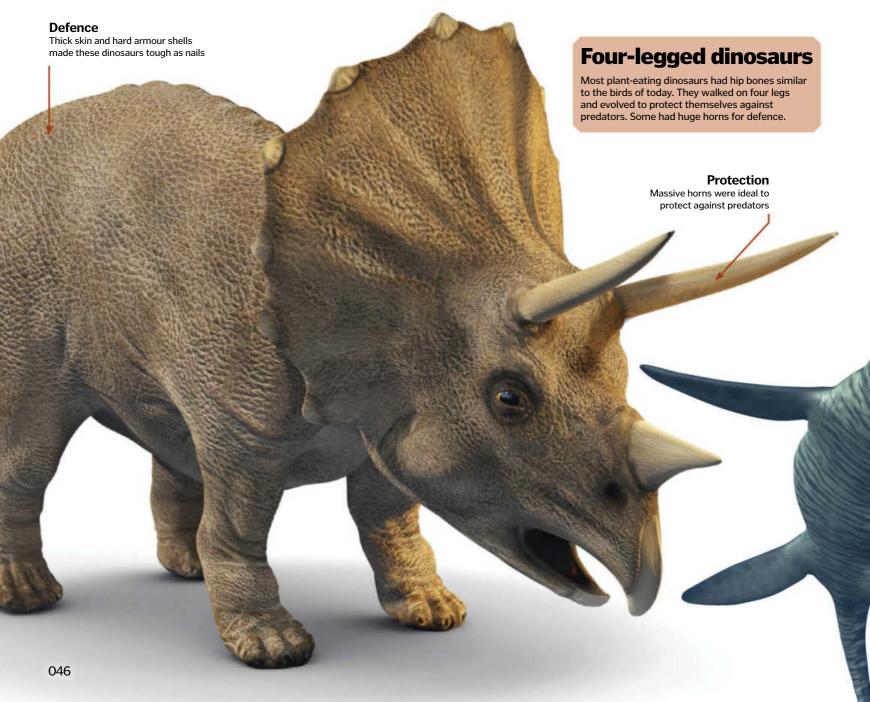

What was a dinosaur?

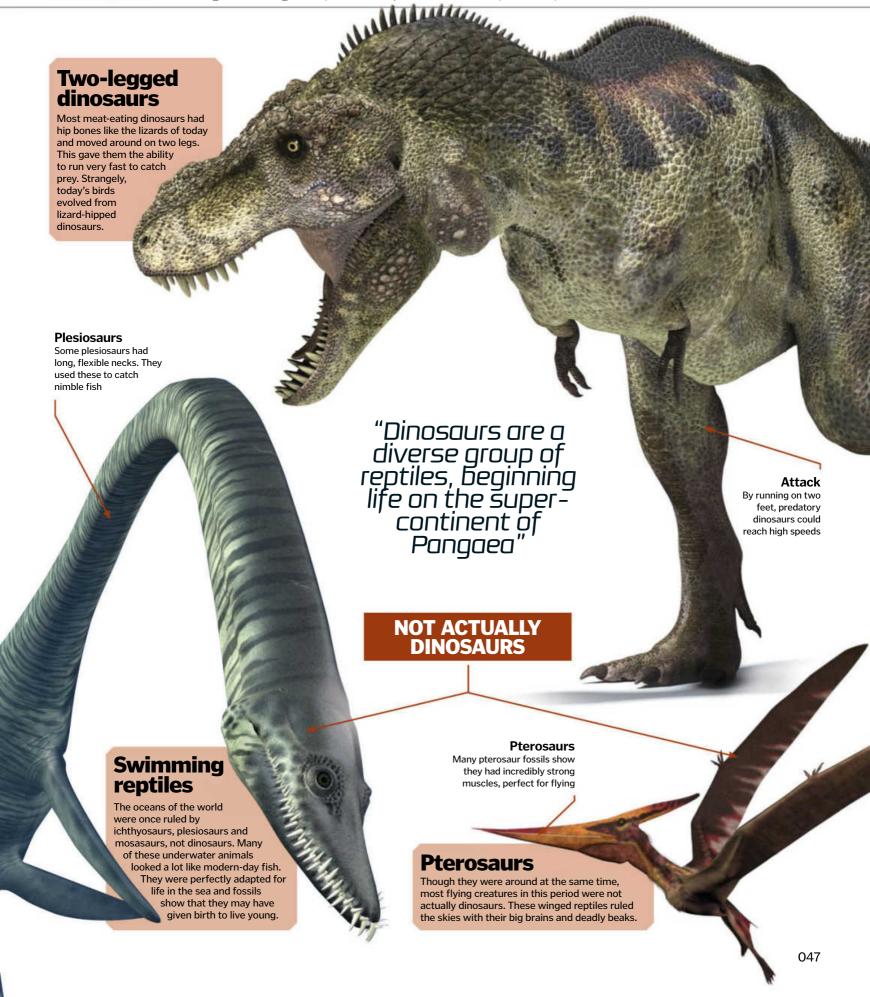

Dinosaurs were a reptile that first appeared over 230 million years ago. They lived on Earth longer than any other creature in history

Dinosaurs dominated the Earth for over 160 million years, often as the apex predators of their particular environments. Although fossilised dinosaur remains have been discovered throughout human history (early discoveries probably being the origins of mythical creatures such as

dragons and hydras), dinosaurs were only described scientifically in the early nineteenth century. It was British palaeontologist Sir Richard Owen who coined the taxon Dinosauria in 1842. The word dinosaur means "terrible lizard", but the term is somewhat misleading, as dinosaurs are not lizards but are

part of a separate group of reptiles altogether. Dinosaurs are a diverse group that began life on the super-continent of Pangaea. As continental shift progressed and Pangaea broke up into smaller landmasses, dinosaurs became strongly diversified. It's a wonder that Triceratops and T-rex share a common ancestor.

How did the dinosaurs' world evolve?

Jurassic period

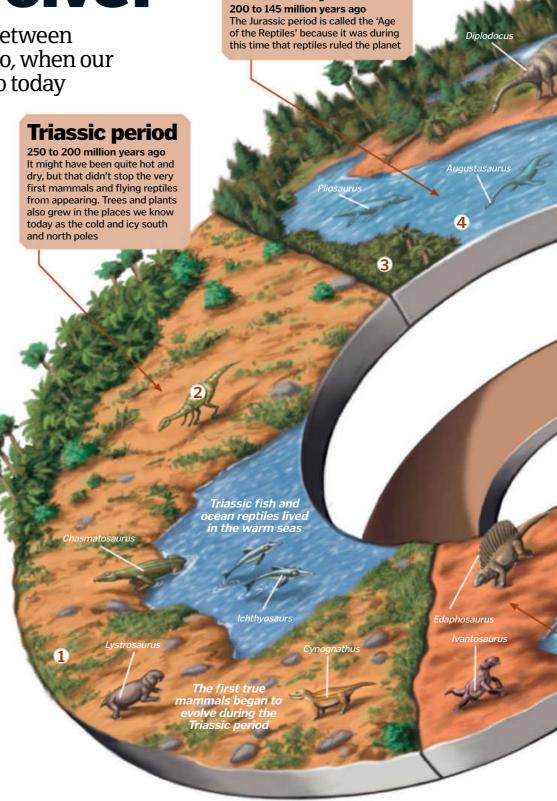

Dinosaurs roamed Earth between 230 and 65 million years ago, when our planet was very different to today

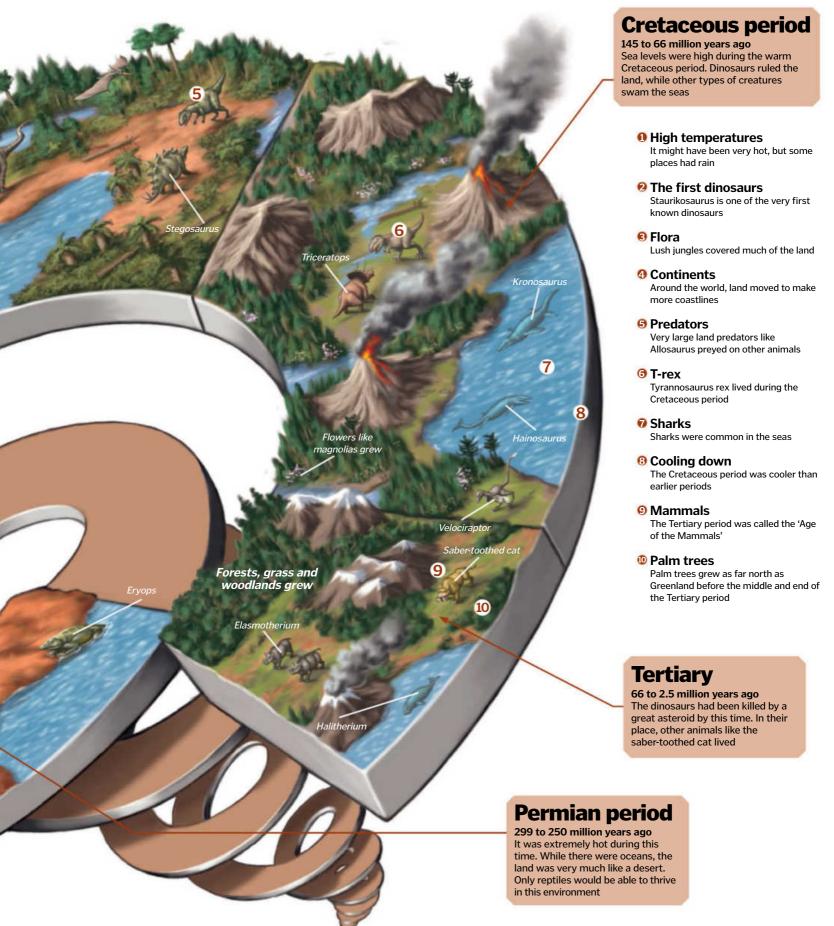

era, and the subsequent destruction of the ancient coal swamps that were home to a great many Carboniferous plants, meant that the Mesozoic (or 'middle life') era signalled something of a recovery period in Earth's history. Comprising the Triassic, Jurassic and Cretaceous periods, the Mesozoic era was less dry but was still swathed in high global temperatures, and the now-empty ecosystems on the land were soon taken over by evolving mammals and dinosaurs. Meanwhile, beneath the oceans, new corals appeared and various sea urchins began to diversify and thrive, having been almost driven to the point of extinction at the end of the Permian era.

The ultra-dry climates of the Permian

Some estimates put some of the more tropical temperatures during the start of the Triassic period (at the beginning of the Mesozoic era) as high as 38°C (100°F), and at this point the world's land masses were still combined in one large supercontinent called Pangaea. During the Triassic period, Pangaea gave rise to climatic zonation, with some areas becoming extremely dry and others experiencing monsoon-like conditions. As a consequence of this climatic zonation, plants began to separate into northern and southern realms.

By the time of the Jurassic period, global temperatures had dropped to around 30°C (86°F) and Pangaea had separated into northern and southern parts. The oceans as we know them today really started to take shape during the Cretaceous period – so-called because of the large chalk content in the shallow seas as a result of the build up of algae skeletons. Following the major extinctions at the end of the Cretaceous period, mammals – which were previously small and insignificant compared to the dinosaurs – were now able to exploit many of the vacant ecosystems and gradually come to dominate the planet.

Where did dinosaurs live?

Dinosaurs lived all over the world, from dry, dusty deserts to wet, sweaty swamps. Explore five different habitats that dinosaurs called home...

First dinosaurs

The weather of the Triassic period helped dinosaurs to develop. Their bodies were much better suited to hot and dry conditions compared to mammals

Plants

Only plants that could live without lots of water survived in these areas. There wasn't much for herbivores to eat

053

Jurassic swamp 200 to 145 million years ago Sea levels were higher during the Jurassic period. Some land got flooded, which created muddy swamps

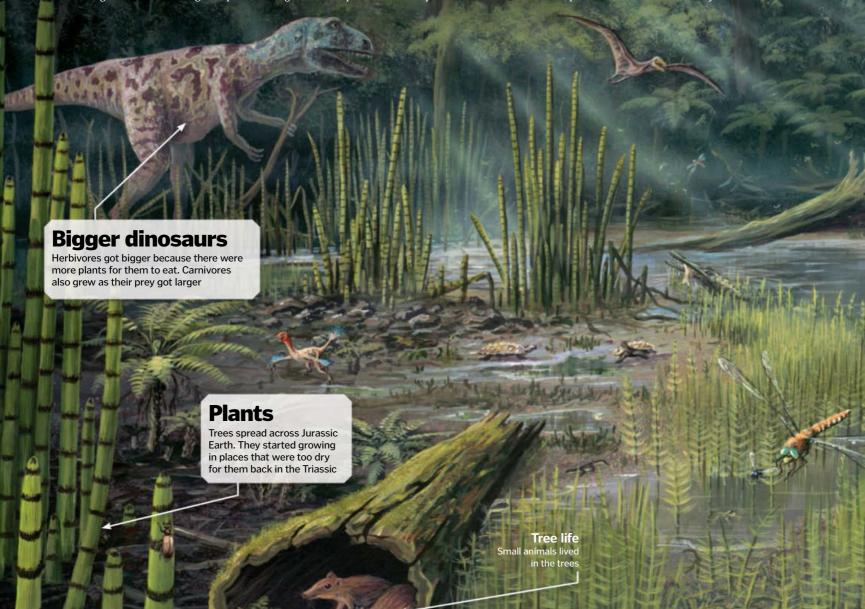

During the late Jurassic period, the Earth's temperatures had cooled to around 30°C (86°F), declining still further later on in the period, and the Earth began to experience seasonality, with extremely hot summers and unbearably cold winters. Nevertheless, the Jurassic period is when life on Earth thrived, with large dinosaurs roaming the land, huge reptiles dominating the seas and winged reptiles ruling

054

the skies. The oceans were teeming with new predators, including ammonites, belemnites and a range of shell-crushing fish.

One of the most formidable predators of this period was the Allosaurus. With a large skull full to the back with sharp, serrated teeth and three large claws on either hand that may have been used to grip onto its prey, many believe that the Allosaurus hunted stegosaurs, ornithopods and sauropods - creatures that

devoured the plants native to the planet's swamps. Stegosaurus is perhaps the bestknown stegosaur and was so-called because of the strange, diamond-shaped plates running down its back (Stegosaurus means 'plated lizard'). While many assume that these plates were for defence, the two pairs of long spikes that projected from the tip of the tail were much more likely for this purpose, rendering the plates little more than fancy decorations.

Cretaceous plains

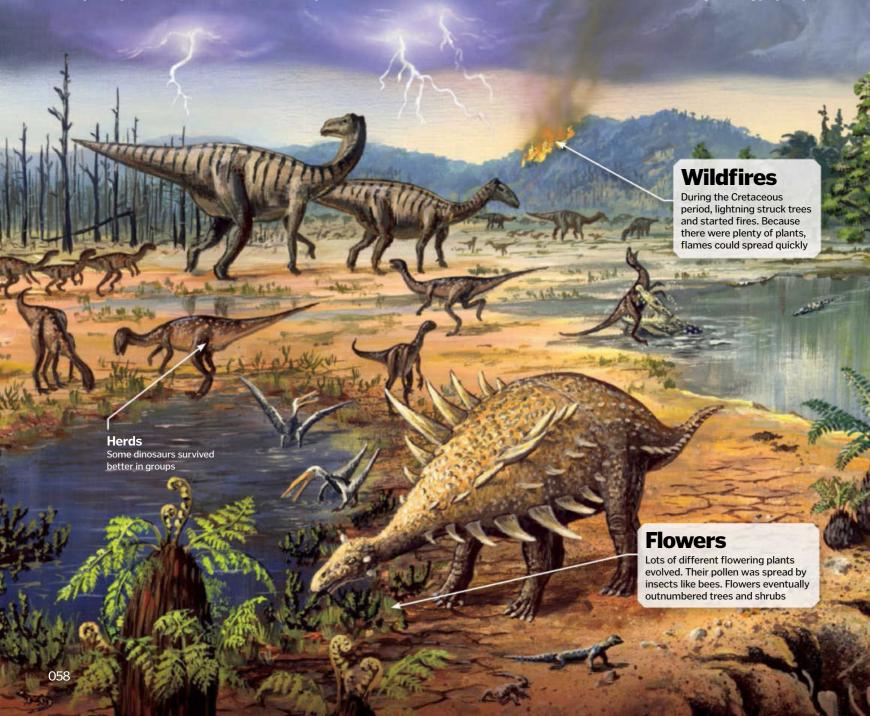

145 to 66 million years ago

Life was not easy on the Cretaceous plains. Dinosaurs faced many changes to their habitat

The climate of the Cretaceous period consisted of global temperatures of around 10°C or 50°F higher than today and high atmospheric carbon dioxide levels. It was something of a greenhouse world. The high sea levels (approximately 200-300m higher than today) meant that swamp-like plains existed on the lower latitude areas where crocodylomorphs, such as the Simosuchus and

Deinosuchus, began to thrive. The Deinosuchus, a member of the alligatoridae family that includes modern day alligators, weighed up to ten tons and was one of the most ferocious predators in North America. In fact, its habitat overlapped with tyrannosaurids, such as Daspletosaurus; in these ecosystems it was the powerful alligatorid, not the tyrannosaurids, that dominated.

Also during the Cretaceous period, the skies were inhabited by colossal pterosaurs, such as the Quetzalcoatlus. These beasts rank as the largest flying creatures of all time, with a wingspan larger than many small planes However, thanks to a complex system of air sacs inside its bone structure, the Quetzalcoatlus weighed no more than 250kg. They were agile and fast in the air, making catching prey easy.

059

The dinosaurs' neighbours

Tiny mammals lived alongside dinosaurs in the Mesozoic era. While many are now extinct, some of their descendants are still alive today

Mammals are characterised in many different ways, such as the possession of hair and mammary glands that produce milk for their offspring. While it is the formidable dinosaurs that people associate most with the Mesozoic era, mammals also lived and evolved during this era. For example, during the early Cretaceous

060

remaining monotremes. They are found only in Australia, where the Teinolophos lived around 120 million years ago.

Going further back into the late Jurassic period, there existed the Multituberculata - a small rodent-like mammal that occupied the northern hemisphere. Examples of these mammals include Ptilodus, which largely resemble onto the bark of trees and feet that can be reversed backwards to allow the animals to climb down trees with their heads pointing downwards. Here are just a few example of the mammals that existed

What's inside a dinosaur egg?

Just like modern day baby chicks, dinosaurs grew and hatched from eggs to roam the planet a very long time ago

Contract of the second

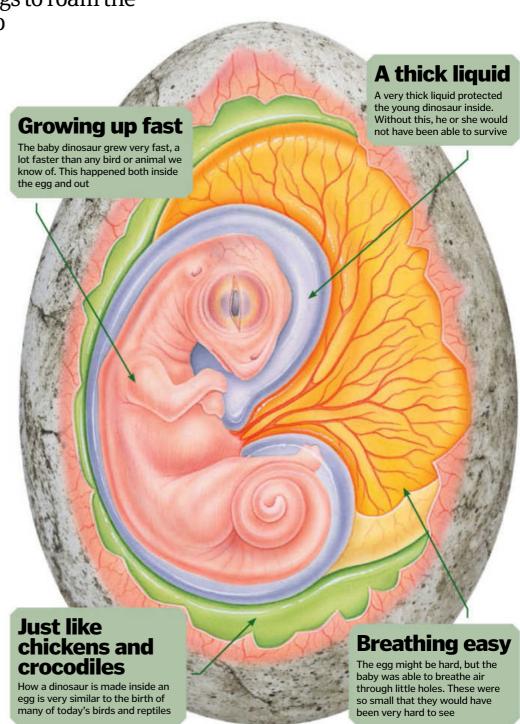

What came first – the dinosaur or the egg? We're not entirely sure, but what we do know is that these great reptiles

laid eggs just like chickens do. Inside the shell of a hen's egg, chicks are able to grow before they're ready to hatch. That's just how the dinosaurs were born.

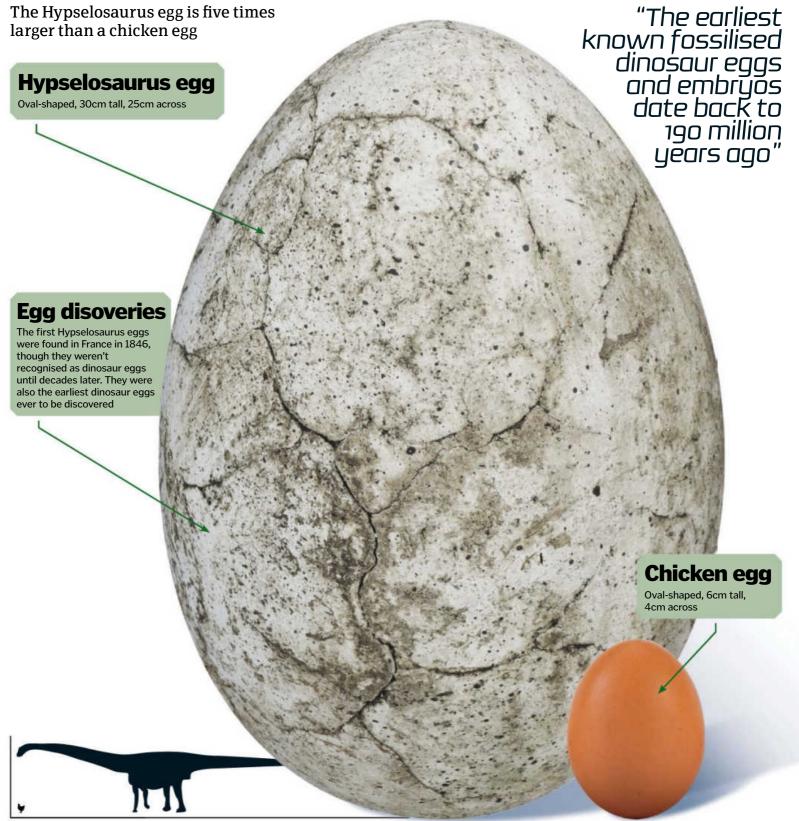

We know that baby dinosaurs were made this way because we have found lots of evidence. Fossilised dinosaur eggs have been found at over 200 places across the world. They tell a story about how the dinosaur made its nest, laid its eggs and how baby dinosaurs were born.

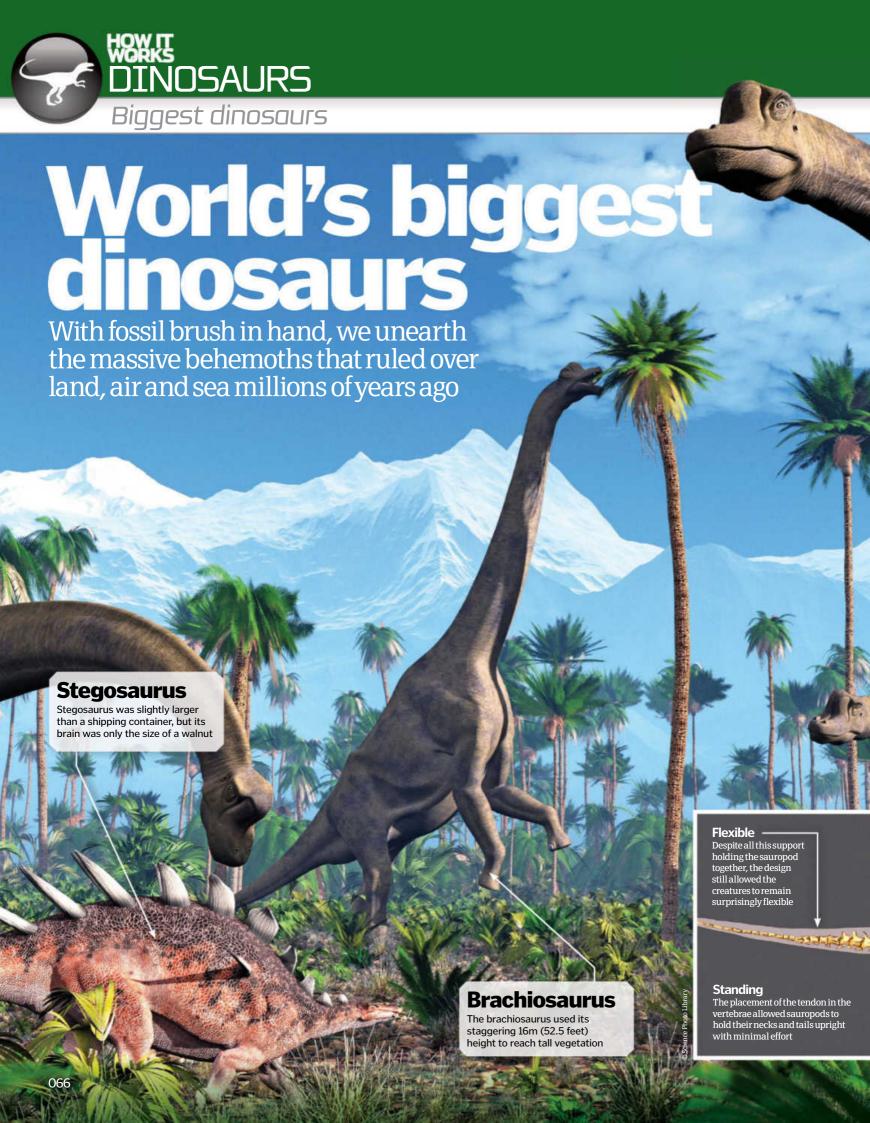

A crew of palaeontologists exploring Mongolia in 1923 were the first to scientifically recognise fossilised dinosaur eggs for what they were. Since then many dinosaur nesting sites for many different species have been uncovered all around the world. The oldest known dinosaur eggs and embryos date back to the Early Jurassic (about 190 million years ago) and come from the Massospondylus, a bipedal, omnivorous prosauropod.

Egg Mountain in Montana, USA is the site of one of the most famous dinosaur nest discoveries. Maiasaura remains were found near a nest with the remains of eggshells and babies too large to be hatchlings and this is the reason why Maiasaura is known as "caring mother lizard". Maiasaura and many other species of dinosaur, raised their young in nest colonies. This relfected the way that they herded when on the move. This amazing discovery was the first proof that dinosaurs raised and fed their young, rather than leaving hatchlings to fend for themselves like modern turtles do. Nests contained approximately 30-40 eggs and were not incubated by the parent sitting on them, but by the heat produced from rotting vegetation placed in the nest. It's thought that Maiasaura hatchlings left the nest after a year or two of rapid growth.

Dinosaur egg versus chicken egg

Contract of the second

It's somewhat frightening to imagine what it must have been like to wander around the plains of

Africa and Argentina 100 million years ago. Whereas today you'd be hard-pressed to encounter a beast any bigger than yourself, back then you'd be running for your life as bus-sized creatures roamed free, some remaining largely peaceful and distant, others full of aggression.

The biggest land-based animal alive today is the African bush elephant, with the largest weighing a measly 13.5 tons and measuring 10.6m (34.8ft) long and 4.2m (13.8ft) high. Argentinosaurus, the current official record-holder for largest dinosaur of them all, would have been at least four times the size. It was a sauropod, dinosaurs of the Jurassic and Cretaceous period that were mostly herbivores and known for being very large. Indeed, many other types of sauropod would have stood tall above the African bush elephant, as would raptors and pterosaurs.

Dinosaurs inhabited the Earth for much longer than any modern animal, from 251 to 65 million years ago, allowing plenty of time for certain species to develop into the giant hulks of flesh we now so revere. The biggest dinosaurs discovered to date have largely been determined to live in the Late Cretaceous period, 99.6-65.5 million years ago, before they faced extinction.

For a long time, though, palaeontologists have wondered why dinosaurs grew to be so large. While impressive, size can also be a

hindrance. Not only does a large animal need a much higher rate of metabolism, but it must also develop much stronger bones and skeletal structures to be able to hold itself upright. Many of these gigantic animals were also cumbersome and slow, leaving themselves open to attack from large predators. Why did dinosaurs continue to grow for millions of years, then?

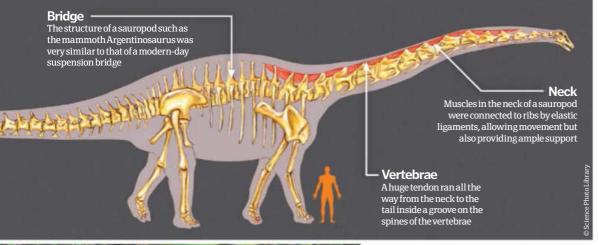

One train of thought is that there was a huge surplus of carbon dioxide in the atmosphere during the age of the dinosaurs. This meant that vegetation flourished, and herbivores such as the sauropods simply had an over-abundance of nourishment available to eat. While somewhat of a burden in terms of manoeuvrability, their size would certainly have helped to some extent when fending off smaller carnivores. This leads to another proposal from palaeontologists, namely that some dinosaurs grew in size over millions of years as a form of self-defence.

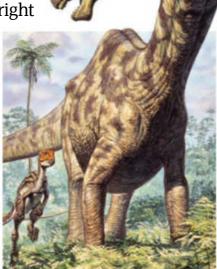

However, others think that these giant dinosaurs were cold-blooded, which was directly responsible for their size. Indeed, warm-blooded animals simply wouldn't be able to sustain such mammoth sizes, somewhat backed up by the lack of mammals larger than a few tons today.

Huge cold-blooded sauropods, weighing in at up to 100 tons, would have been almost self-sustainable, as they could store heat throughout the day for the colder nights, maintaining a fairly unchanged body temperature and prolonging their survival.

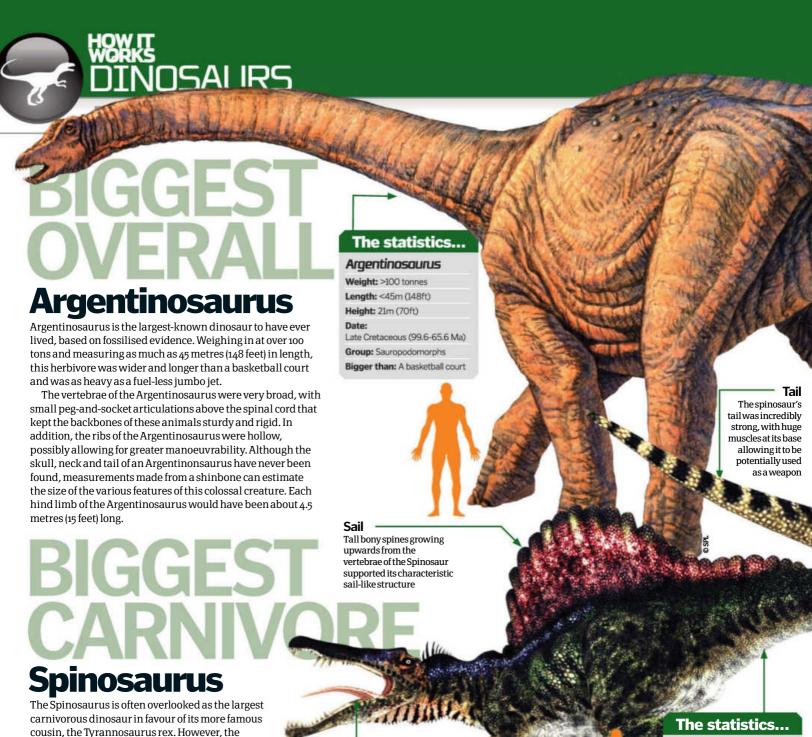

How were they supported?

We examine the anatomy of a sauropod, to see how these huge creatures were able to keep upright

Science Photo Libra

The Spinosaurus is often overlooked as the largest carnivorous dinosaur in favour of its more famous cousin, the Tyrannosaurus rex. However, the Spinosaurus would have dwarfed the popular movie star, measuring 16m (52ft) in length compared to 12m (39ft) for a T-rex. That being said, the characteristic features of the Spinosaurus – namely its fin-like spinal protrusion – make it one of the most recognisable theropods. In the late-Cretaceous period, this 12-tonne creature would have been fairly common, with its sail-like spine adding to a fearsome display and possibly helping to regulate its body temperature.

Teeth

Within its crocodile-like snout, an unusual feature for a theropod, were rows of conical teeth for hunting and killing fish and average-sized land-based dinosaurs

Feet

At the base of the strong hind legs of the Spinosaur were three long, forward-facing claws

Date:

Late Cretaceous (99.6-65.6 Ma)

Group: Theropods

Bigger than:

A double-decker bus

The other contenders

There is some contention among paleontologists as to what the largest dinosaur of all time was. Currently the official record-holder is the 100-tonne behemoth that is Argentinosaurus. However, there have been several other claims to the throne over the years. In the late-19th Century, a paleontologist known as Edward Cope claimed to have found part of a vertebra that suggested he had unearthed a sauropod dinosaur (known as 'amphicoelias') measuring a humongous 62m (203ft). Mysteriously, however, this bone 'disappeared' shortly afterwards, leading some to believe he had falsified the claim to get one over on his chief paleontological rival at the time, Othniel Marsh. It will be interesting to see if any more evidence of this giant creature is unearthed in future. Another contender that little is known about is Bruhathkayosaurus, which may possibly be the heaviest dinosaur ever discovered, coming in at up to a gigantic 220 tonnes.

Although not technically regarded as 'dinosaurs', pterosaurs were around at a similar time and are often (somewhat incorrectly) referred to as 'flying dinosaurs', much to the ire of some palaeontologists. Nevertheless they were impressive creatures, and none more so than Quetzalcoatlus, the largest flying animal of all time. Its huge 2.5m (8ft) skull housed an elongated mouth that was used to hunt land animals including dinosaurs and other vertebrates. Despite its size Quetzalcoatlus was comparatively light as its bones were comprised of a series of air sacs, a useful feature for such a colossal creature aiming to take to the skies. While most other pterosaurs fed on fish, Quetzalcoatlus was somewhat unique in its hunting of land animals, no doubt useful nutrition to fuel its giant metabolic needs.

Dinosaur identification

We spoke to Mike Benton, Professor of Vertebrate Palaeontology in the School of Earth Science at the University of Bristol, UK, to find out how palaeontologists can estimate the size of a dinosaur from fossils and more

How It Works: Can you describe your current role within the world of palaeontology?

Mike Benton: I work in a 50:50 teaching and research position - I teach undergraduates, both geologists and keen palaeontologists, and especially I teach Masters and PhD students. Every year, some 20-25 new Masters students and four-five new PhD students come from all parts of the world to work with us. and I really enjoy working with them to help them develop their careers. In research, I work on several topics by myself, on others with my students, and on others with collaborators around the world.

Could you briefly summarise the kev methods and techniques used in the identification of prehistoric creatures?

Palaeontologists identify fossils based on the existing knowledge of living and extinct forms. The fossils are often incomplete, and usually show only the hard parts, such as shells and bones. But, if there is a living relative, these parts can be identified, and a fair attempt made to identify what the fossil is. Usually, palaeontologists have many fossils of the same animal or plant to work with, and they can compare these.

Can you describe some of the challenges involved in identifying a dinosaur?

Dinosaurs are all extinct, and their closest living relatives, the birds, are so different that it is hard to make useful comparisons in many cases. But, when complete skeletons are known, all the bones can be identified from knowledge of living forms, and the skeleton can be reconstructed. This usually shows basic things, such as whether the animal walked on all fours or on its hind limbs only, what it ate (are the teeth sharp or not?), and

whether it could have used its hands for grasping things.

How are paleontologists able to discern how large a dinosaur is, and how can they estimate a dinosaur's diet?

The dinosaur skeleton will itself be large or small. The best guide to body weight for a fossil form is to measure the leg bones. The femur (thigh bone) is particularly useful - because weight (= mass) is a three-dimensional measure, we look for something that increases and decreases in proportion to mass, and that is the diameter of the femur. So you get a good relationship between femur head diameter and body mass from living birds, crocodiles and mammals, and dinosaur body weights can then be estimated from this regular relationship. Diet is determined from overall tooth shape - curved and pointy for meat-eating, and broader for plant-eating. It's hard to be more precise, because we don't have the data set of comparative information to tell exact plant food from wear marks and scratches on the tooth enamel (used for determining the exact diet of mammals).

What, in your opinion, are the most important discoveries made in the past 50 years?

Well, first, the realisation that dinosaurs were active and dynamic animals, dating from the work of John Ostrom in 1969 on Deinonychus, and Bob Bakker in the Seventies on dinosaur warm-bloodedness. Second, the paper by Luis Alvarez and colleagues in 1980 that showed the first evidence that the Earth had been hit by an asteroid 65 million years ago. This has been much confirmed since then, and even the crater has been identified, all showing the key role of this in causing the extinction of the dinosaurs.

How did dinosaurs defend themselves?

Dinosaurs evolved spikes, horns and even thick armoured skin to protect themselves. They needed to be able to fight off predators or risk getting eaten

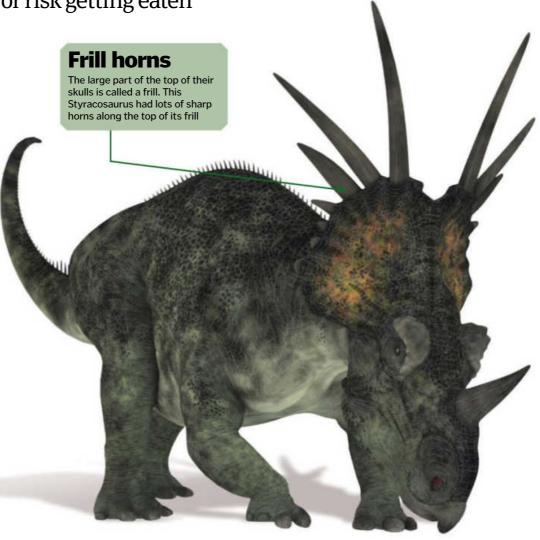

Herbivorous dinosaurs developed built-in weapons to defend against carnivores. This gave them a better

chance of surviving a fight against predators. It also gave them a better chance at defending vulnerable young against predation. Some dinosaurs had sharp claws on their hands, like Iguanodons, which could have been used as a tool and as a weapon. Dinosaurs like Triceratops had horns as long as a human arm that pointed forwards so that the Triceratops could take on its enemy head on. Both these defences could have been used to stab attacking predators.

Other dinosaurs used their tails as weapons. The Ankylosaurus had a heavy, bony hammer at the end of its tail. They could use this to smash into an attacking dinosaur and they were strong enough to crush skulls and break bones. Some dinosaurs were covered in tough scales like a thick coat of armour. Stegosaurus had a row of bony plates running along its spine that are thought to be used for temperature control, though it's certainly possible that they were also used for defence. The bony plates ended along the tail but Stegosaurus remained well defended by the sharp spikes at the end of its tail. Powerful muscles could propel those spikes into an oncoming attacker. Indeed, Allosaurus remains have been found with wounds that line up perfectly with the dimensions of a Stegosaurus's tail spikes

Larger herbivores used their size as a defence. Dinosaurs like the Diplodocus were so massive that carnivores couldn't attack them easily. For smaller dinosaurs, running away was usually the best defence. They developed lighter bones so they could run faster. They needed to escape quickly to avoid fighting altogether.

Tail spikes

Tail spikes could be used as weapons because they were hard and sharp. They also made dinosaurs much harder to eat.

Whin

Dinosaurs like Diplodocus had long tails that they could use like whips. It's possible that they snapped faster than the speed of sound.

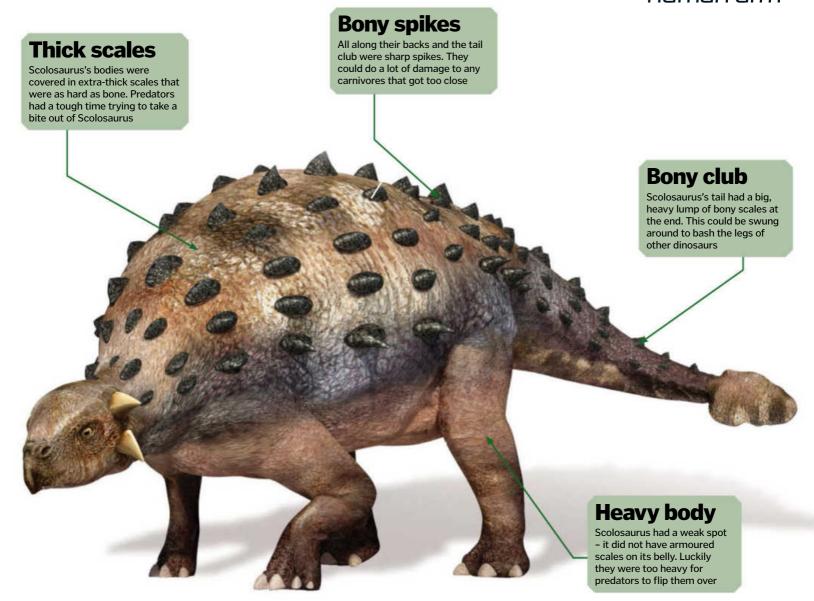

Tail club

Tail clubs were swung around just like a hammer. They were smashed into predators' legs and could crush bones.

Armour plating The Scolosaurus had a body built for

The Scolosaurus had a body built for defence - from a bony club at the end of its tail to thick scales covering its body

"Triceratops had pointed horns on its face as long as a human arm"

Horns

Horned dinosaurs might have charged towards predators to try and scare them away. Their horns could have ripped through skin.

Crest

Head crests were used for communication.

Dinosaurs could make warning calls to each other if they saw a predator nearby.

Headbutt

Some dinosaurs, like
Stegoceras, could smash
skulls with predators. Their
heads were protected by extra
layers of bone for shock-absorption.

What was the cleverest dinosaur?

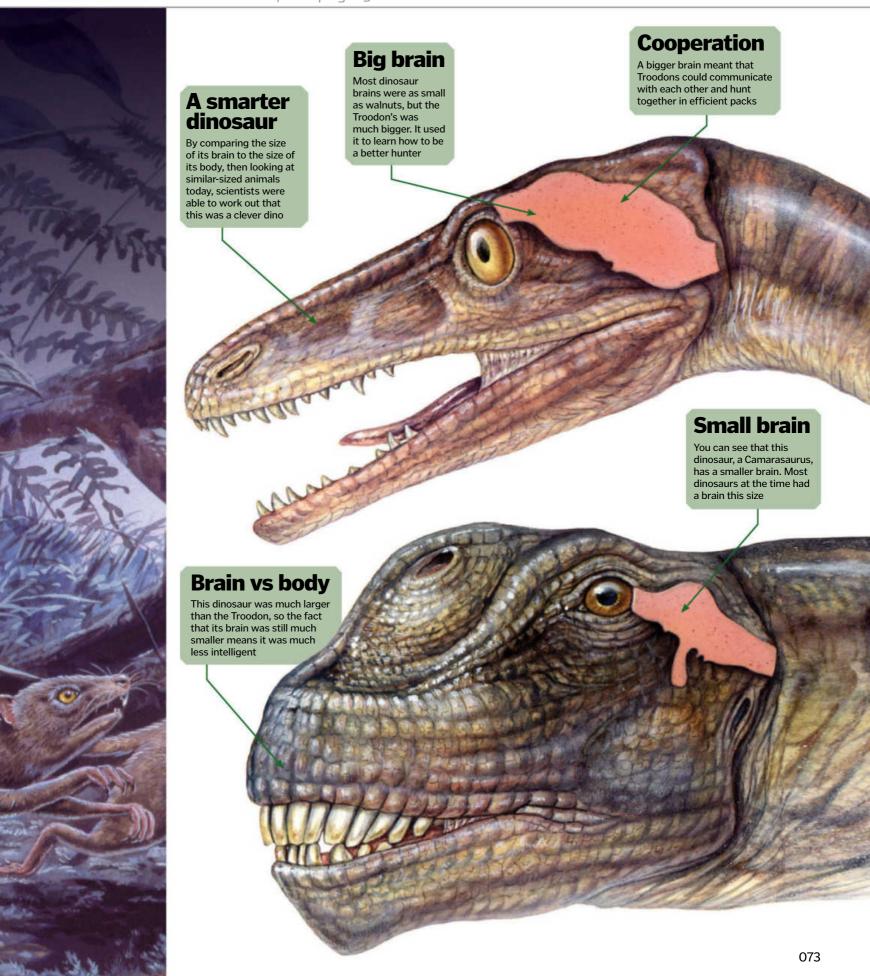

The Troodon was about the same size as a human, but their brain was much bigger than the other dinosaurs'. This made them very dangerous hunters

Dinosaurs were not a brainy bunch, but the Troodon was unusually smart. Its brain was much larger than other dinosaurs and it was ferocious predator. They were clever enough to hunt in packs so they could catch much larger prey. There was no escape from a Troodon.

The bird-like dinosaur was very good at running, with its long legs and curved claws that would deliver the killer blow to prey. It is thought that a Troodon's teeth were as sharp as knives and that their big eyes gave them great night vision, so they weren't limited to hunting in daylight.

Thumbs up

Troodons were the most human of all the dinosaurs. They had opposable thumbs and they could walk upright on two legs

Diplodocus

We find out how this mighty dinosaur once lived

Diplodocus is one of the most famous dinosaurs. It belonged to the group known as the sauropodomorphs and

was around in the Late Jurassic period – specifically the Kimmeridgian and Tithonian eras roughly 154-150 million years ago. It reached sizes of up to 25 metres (82 feet) in length and was found in what is now North America. There were four species of Diplodocus, with the largest of these being Seismosaurus, which translates to 'ground shaker'.

Diplodocus was part of the diplodocid family, sharing the same characteristic of having 15 neck vertebrae, short forelimbs compared to the rest of its body and a whip-like tail. Its giant neck made up a large proportion of its body, but there is still some contention as to whether it held its neck vertically or horizontally. Its rectangular skull contained huge eye sockets and nasal chambers. Studies of its teeth suggest that Diplodocus fed using what is known as branch stripping, where the branch of a tree is grasped in a creature's jaw and then pulled sharply up or down, tearing off foliage.

Diplodocus was the largest dinosaur around. It was later eclipsed by other sauropods, but it roamed the tallest for at least a few million years. Numerous bones have been found and studied by palaeontologists, providing an insight into how these giant dinosaurs were able to support themselves and how they lived.

Vertebrae

Spine

its vertebrae

Running along its back,

were triangular spines on

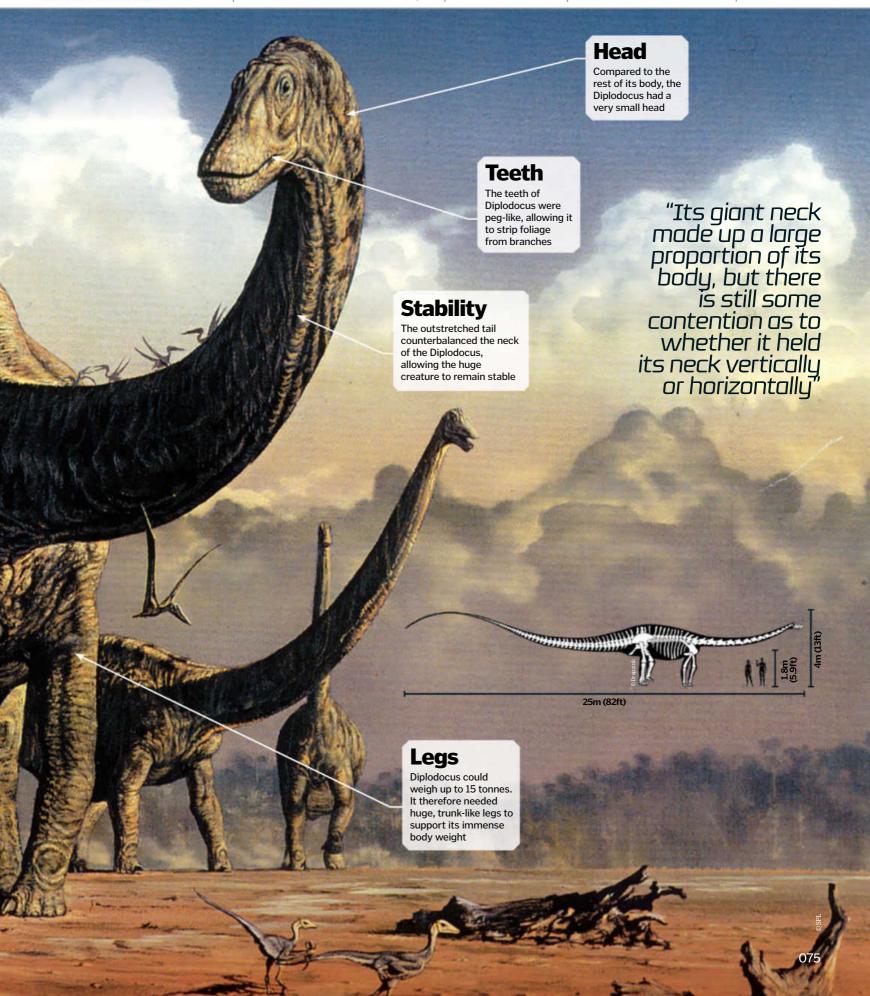

like other sauropods,

There were as many as 80 caudal vertebrae in the tail of the Diplodocus

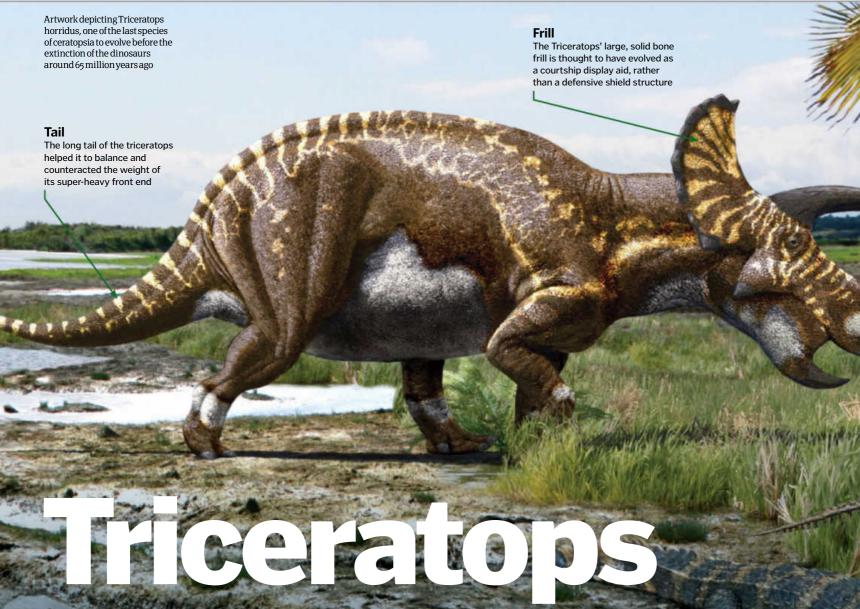

Tail

It's highly likely that it was able to crack its whip-like tail at supersonic speeds, using it as a primary form of attack or defence

One of the most well-known dinosaurs, the Triceratops was a herbivorous titan that was very well equipped for a fight

Triceratops is a genus of herbivorous dinosaur that comprises two validated species – Triceratops horridus and Triceratops prorsus, both of which roamed Earth during the Late Cretaceous period (68-65 Ma) before being eradicated in the K-T mass-extinction event that wiped out all dinosaurs.

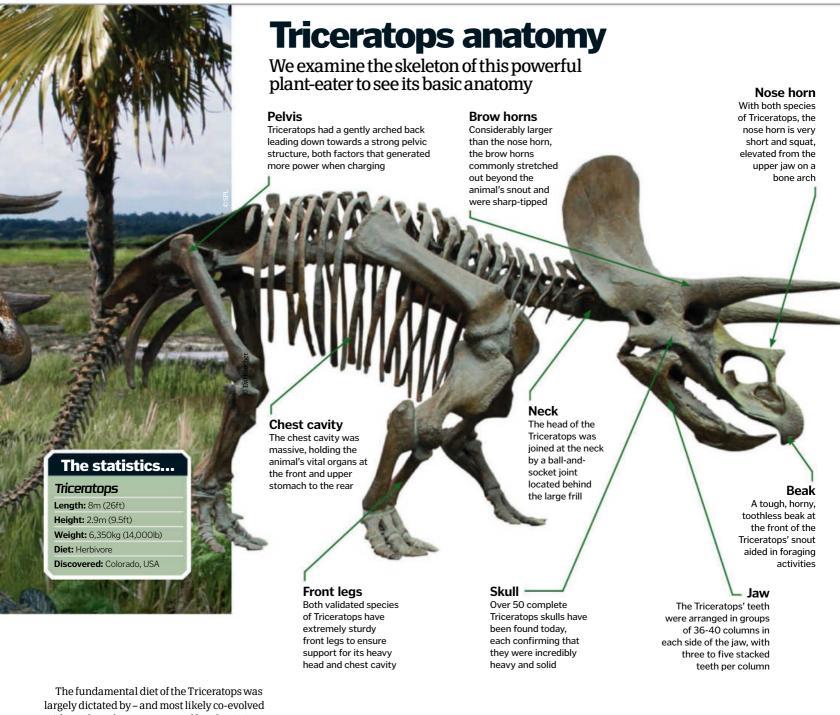

Triceratops were large, rhinoceros-like animals that weighed many tonnes – a fully grown adult would be expected to weigh in the region of seven tonnes. They were heavily armoured with reinforced bone horns, which could exceed 70 centimetres (28 inches) and a solid bone frill, and hugely powerful thanks to their sturdy frame. These traits, combined, made both species of Triceratops a fearsome foe to potential predators, capable of puncturing flesh and shattering bone with their sharp horns when charging.

In terms of anatomy (for a comprehensive rundown, see the 'Triceratops anatomy' illustration), the Triceratops genus is incredibly interesting, not least because many of its parts' functions are still debated today in the field of palaeontology. A good example of this can be seen by analysing a typical Triceratops skull, which – aside from typically measuring a whopping two metres (6.6 feet) in length – sported three horns as well as a fluted, extravagant rear frill.

The horns, from which the genus gets its name, and frill have been successfully argued by palaeontologists to have been used for self-defence against predators, with close examination of unearthed specimens revealing battle scars, cuts, punctures and cracks. However, modern scholars also postulate that both skull features, along with the elongated nature of the skull itself, most likely

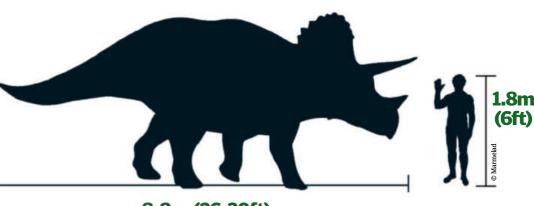

also evolved as courtship aids, with potential mates selected on the size and shape of these features. It has also been suggested that the frill may have helped Triceratops regulate their body temperature in a similar manner to the plate-laden Stegosaurus (whose name translates as roof, or covered, lizard).

Other anatomical areas of interest lie in this dinosaur's large bird-like beak and hips. Indeed, it is because of these particular features that this genus has been used as a reference point in the definition of all dinosaurs – ie all dinosaurs are descendants of the most recent common ancestor of Triceratops and, as such, this common ancestor is also that of birds prevalent throughout the world today. It's important to note here that modern birds did not descend from triceratops directly, but rather from its common ancestor with all other dinosaurs; today's birds in fact originate from saurischian dinosaurs.

largely dictated by – and most likely co-evolved with – its low-slung posture and head position, which was located close to the ground. As a consequence of these factors, as well as its deep and narrow beak and sharp teeth batteries, both species of Triceratops most likely consumed large amounts of low-growth ferns, palms and cycads, plucking the plants with their beaks and then shredding the fibrous material with their teeth.

The Triceratops' main potential predators were carnivorous theropod dinosaurs such as the Tyrannosaurus rex. However, while modern-day depictions of these two prehistoric titans are often far-fetched, Triceratops specimens have been discovered with T-rex bite marks and even one where the herbivore had had one of its brow horns snapped off entirely.

8-9m (26-30ft)

Velociraptors have been ingrained in public consciousness since the 1993 movie *Jurassic Park* showcased them as the most fearsome of apex predators. Smart, lethal and bloodthirsty, the Velociraptors of the film arguably stole the show. However, the movie was famed for its indulgence of artistic licence, with palaeontologists bemoaning the lack of historical accuracy.

So what were these dinosaurs really like?
Velociraptor, of which there are two verified species
– V mongoliensis and V osmolskae, was a genus of
dromaeosaurid ("running lizard") theropod
dinosaur that lived in the Late Cretaceous period,
about 75-71 million years ago. They were two metres
(6.6 feet) long, just under a metre (three feet) high,
feathered and bipedal, running on two of their three
toes per foot. Velociraptors were native to modernday central Asia most notably Mongolia), where they

built large, ground-based nests to protect their vulnerable young.

Velociraptors, though often living in close proximity to one another, were largely solitary and, while certain finds suggest they could have teamed up while chasing their quarry, they were not pack hunters, with evidence showing they would fight among themselves for feeding rights. In addition, their staple diet consisted of animals of equal size and weight to themselves or those smaller than them, with very little evidence suggesting they would attempt to bring down larger dinosaurs, such as the Tyrannosaurus rex à la

Velociraptor hunting techniques revolved largely around their speed and agility. They could accelerate up to 64 kilometres (40 miles) per hour and pounce long distances, as well as grip prey firmly with their unique, sickle-shaped claws (notably

their enlarged 'killing claw'). These traits were partnered with a tendency to ambush prey, rather than tackle their victims face on or from long range (see the 'Slash or subdue?' boxout for more). Interestingly, however, while there's no doubt that Velociraptors hunted live prey, unearthed fossilised evidence suggests they were also incredibly active scavengers, with the species frequently feeding on carrion (pterosaur bones have been found in velociraptor guts, for instance) and carcasses left over by other predators.

Velociraptors died out along with the remaining species of dromaeosauridae in the run up to, and as a result of, the Cretaceous-Tertiary mass-extinction event that occurred approximately 65.5 million years ago. Despite this, elements of their anatomy and appearance can still be seen today – albeit in heavily evolved forms – in many species of bird.

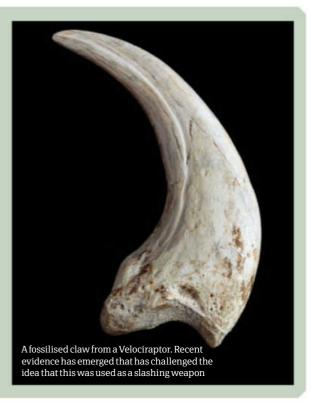

Slash or subdue?

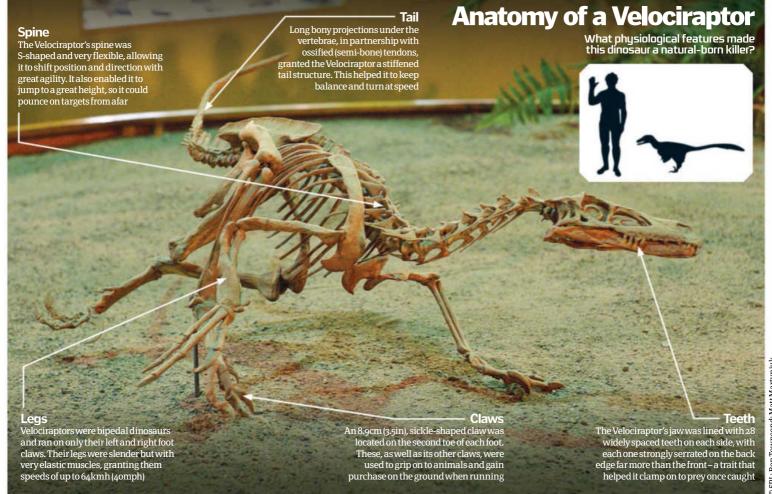

Did Velociraptors use their sickleshaped claws to disembowel prey or for some other purpose?

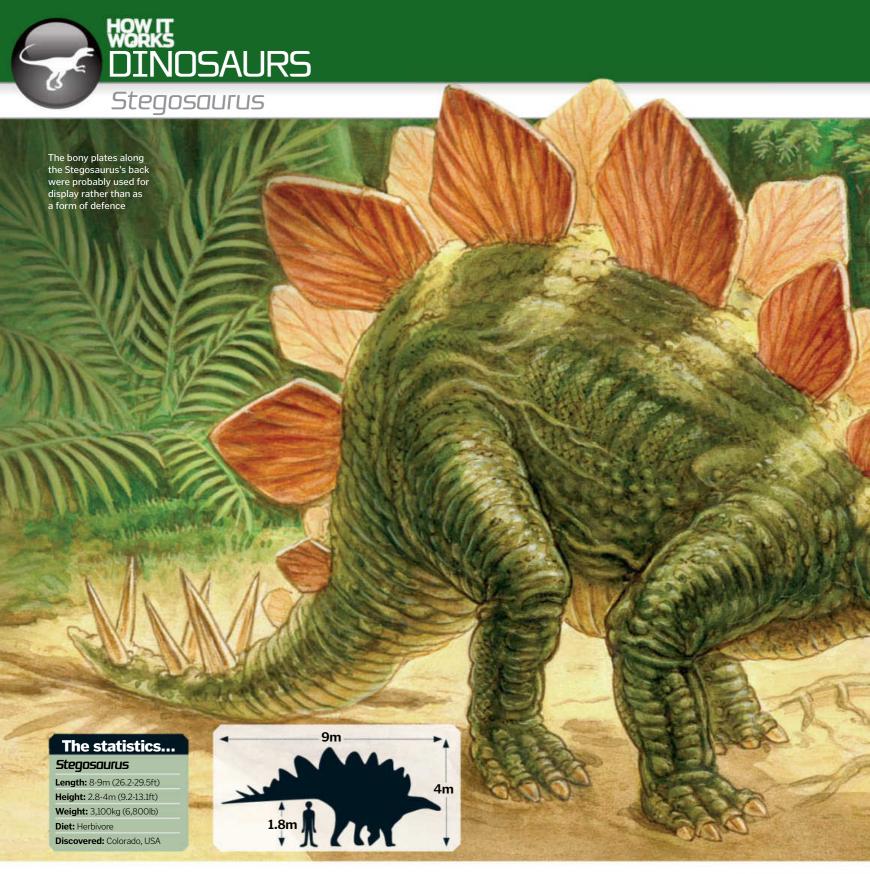

The majority of non-avian theropod dinosaurs are characterised by razor-sharp serrated teeth and talon-like recurved claws, the Velociraptor being no exception. Armed with a bounty of claws on both its hands and feet, the Velociraptor at first glance seems to be the perfect killing machine, capable of rapidly chasing down prey before shredding their flesh with one of their knife-like tools. Well, that was at least the commonly accepted theory among palaeontologists until late in 2011, before a new study by a team of international dinosaur experts suggested an entirely different use for them.

The study suggested that far from their claws specifically the Velociraptor's much-touted 'killing claws' - being used to shred and slice prey in order to kill them prior to consumption, they were far more likely to be used in a similar way to the talons of modern-day hawks and eagles. This entails the birds using their talons as a gripping tool, snaring prey of a lesser body size, pinning them down with their own body weight and then often consuming them live with their beaks.

This theory is seemingly backed up by the $Velociraptor's \, feet \, showing \, morphology \, consistent \, with \, a$ grasping function, supporting a prey immobilisation model rather than the originally assumed combative one.

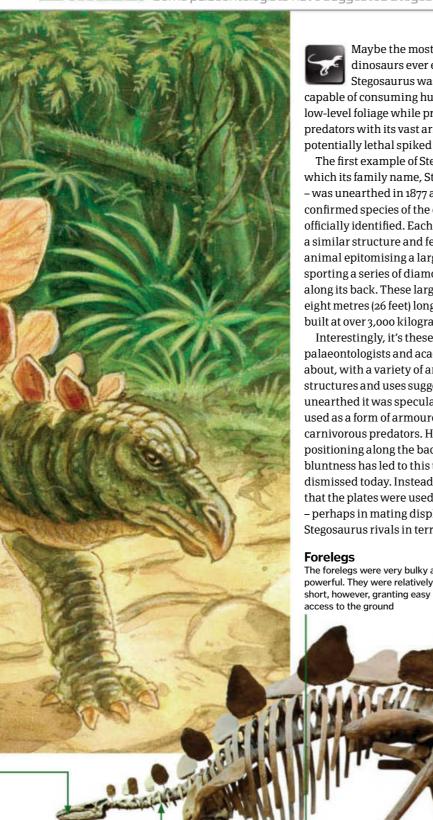

Stegosaurus

One of the most well known of the dinosaurs, the Stegosaurus boasted a series of diamond-shaped bone plates and a tail that could kill

Skull

Despite its large scale, the Stegosaurus's head was very narrow and it had a tiny brain capacity

Neck

Due to its herbivorous diet, the neck angled

downwards, allowing the

animal to eat low-level

vegetation easily

Maybe the most iconic genus of dinosaurs ever excavated, the Stegosaurus was a herbivorous titan,

capable of consuming huge quantities of low-level foliage while protecting itself from predators with its vast armoured frame and potentially lethal spiked tail.

The first example of Stegosaurus - from which its family name, Stegosauridae, derived - was unearthed in 1877 and since then four confirmed species of the dinosaur have been officially identified. Each species demonstrates a similar structure and feature set, with each animal epitomising a large quadruped, sporting a series of diamond-shaped plates along its back. These large creatures were over eight metres (26 feet) long and were heavily built at over 3,000 kilograms (6,614 pounds).

Interestingly, it's these plates that palaeontologists and academics know the least about, with a variety of arrangements, structures and uses suggested. When first unearthed it was speculated that they were used as a form of armoured defence against carnivorous predators. However, their positioning along the back and apparent bluntness has led to this theory being largely dismissed today. Instead, academics suggest that the plates were used as a decorative feature - perhaps in mating displays or to ward off Stegosaurus rivals in territory disputes.

The forelegs were very bulky and

access to the ground

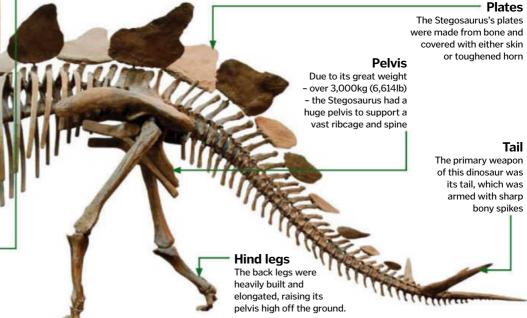

The field of palaeobiology reveals almost everything else about this genus. Studying fossilised evidence it is clear that due to Stegosaurus's very small and narrow skull, they had a tiny brain and so were not very intelligent - something seemingly confirmed by their primitive and mundane feeding habits. The low level of the animal's neck, short but bulky forelegs and raised pelvis/elongated hind legs indicate that Stegosaurus spent much of its daily routine consuming large quantities of low-lying foliage (such as ferns, cycads and conifers). This is confirmed by the shape and formation of its teeth and a low bite force.

Upon closer inspection of the dinosaur's legs it is also clear that it could not move very quickly. This is apparent as the discrepancy in size between the front and hind legs is so great that, if the creature ran at over eight kilometres (five miles) per hour, its longer back legs would cross over the forelegs leading it to fall.

Despite these shortcomings, Stegosaurus wasn't totally defenceless, as it boasted a flexible, armour-plated and spiked tail. Taking Stegosaurus stenops as an example, the dinosaur had four dermal tail spikes of approximately 75 centimetres (29.5 inches) in length each, which extended out from the tail slightly off the horizontal plane. These spikes enabled the Stegosaurus to whip its tail and puncture the flesh of any attackers.

Stegosaurus anatomy

Understand the biological structure of this distinctive dino from the inside out

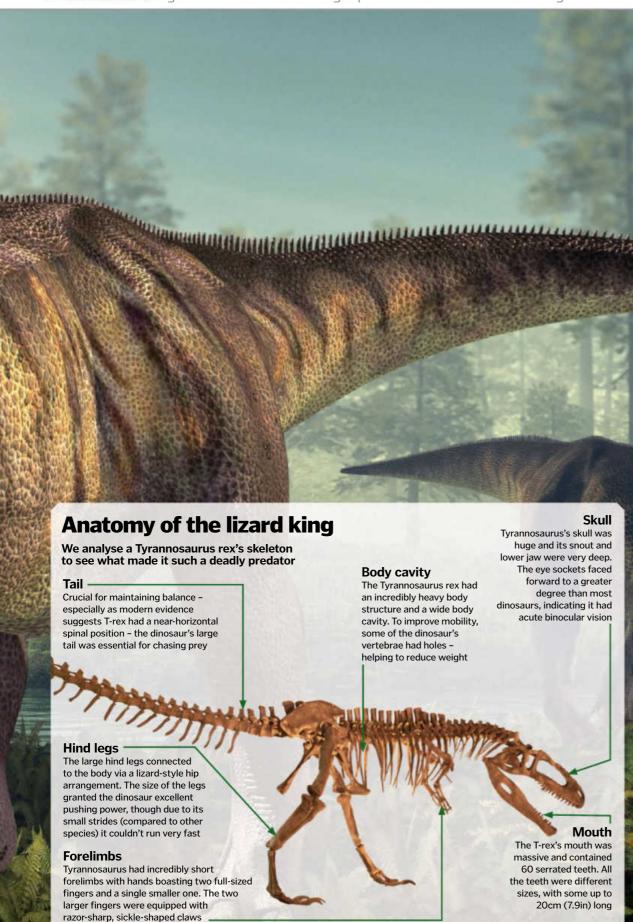

Learn about the lizard king's physiology and how it presided over the prehistoric jungle

Tyrannosaurus rex was a species of Theropoda dinosaur in the Late Cretaceous period. Like other tyrannosaurids – such as Tarbosaurus and Gorgosaurus - the T-rex was a bipedal carnivore and apex predator and scavenger, preying on smaller dinosaurs directly or out-muscling them for their kills. Typical prey included hadrosaurs and ceratopsians.

Tyrannosaurus rex's name translates as "tyrant lizard king" - something that was historically attributed due to its immense size. Indeed, the Tyrannosaurus rex is one of the largest species ever excavated by palaeontologists, with specimens averaging over 12 metres (40 feet) in length and four metres (13 feet) in height, but it wasn't the biggest carnivorous dino. It was incredibly heavy with fully grown adults weighing up to nine tonnes; this figure was suggested in 2011 after an in-depth study which made digital 3D models of five T-rex skeletons.

Due to their considerable size, the Tyrannosaurus rex had very few, if any, predators - a fact that enabled it to remain unchallenged as the Late Cretaceous era's apex predator on land and to live for lengthy periods. Estimates taken from excavated specimens - of which there are now more than 30 confirmed around the world - indicate that the T-rex's life span was roughly 30 years, with the majority of growth taking place in the first 16 years before tailing off rapidly. This suggests that the Tyrannosaurus rex would have reached adulthood at approximately 20 years of age.

As with almost all species of Dinosauria, the Tyrannosaurus was wiped out 65.5 million years ago in the Cretaceous-Palaeogene (K-Pg) extinction event. At the time it was one of the last widespread non-avian dinosaurs, as evidenced by the discovery of many specimens throughout North America.

T-rex mythbuster

Due to a variety of films depicting the T-rex in their own unique way, an accurate view of the species has been clouded. For example, despite being a prominent star of all the Jurassic Park films, Tyrannosaurus rex did not exist in the Jurassic period (199-145 MYA). In fact, it lived millions of years later during the Late Cretaceous (100-65.5 MYA). Further, for decades T-rex has been depicted as having green scaly skin. However, recent evidence suggests its skin colour was varied and, during the early years of its life, it probably sported insulative feathers. The T-rex has also been commonly lauded as the biggest carnivorous dinosaur of them all. This isn't strictly true, with palaeontological evidence suggesting the species Spinosaurus outsized it by over three metres (9.9 feet) in length. And finally, another myth perpetuated in Jurassic Park is that the Tyrannosaurus could run at high speed (ie keep up with a car), but it could probably only manage about 40 kilometres (25 miles) per hour due to its

relatively small strides.

The giant Brachiosaurus

Three times longer and two times taller than a double-decker bus, Brachiosaurus truly was a terrestrial titan of epic proportions

Sa Sa Ea

Brachiosaurus was a genus of sauropod dinosaur that roamed the Earth during the Late Jurassic period

(circa 155-140 million years ago). They are characterised, like many sauropods of the time, by their huge necks and comparatively tiny skulls and brains. Currently only one species has been officially confirmed – B altithorax – though others have been suggested.

Interestingly, like other sauropods, these creatures – despite weighing an estimated 60 tons and measuring up to 30 metres (98 feet)

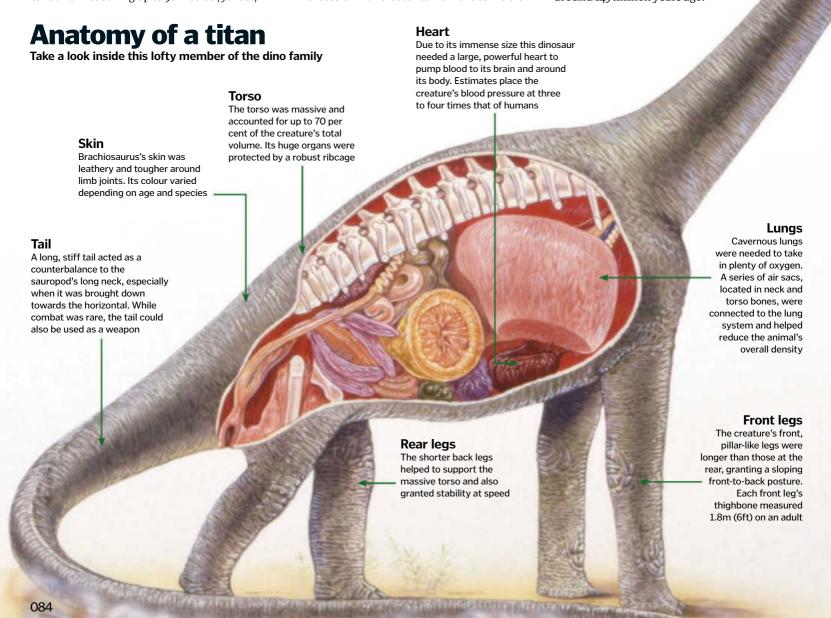

long – were actually colossal vegetarians, with their diet comprising solely foliage.

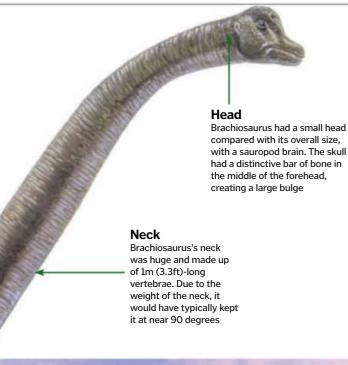

Their evolution of such a long neck (see 'The high life' boxout for more details) seems to be intrinsically linked to their diet, with the elevated head position enabling them to access leaves unavailable to shorter species.

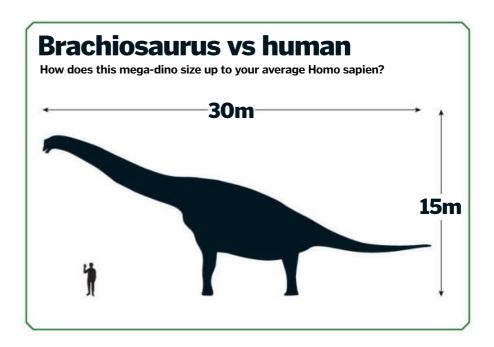

This dominion over a food source is also a major factor behind their generally massive proportions, with millions of years of domination allowing them to grow to sizes far in excess of rival creatures from the same era.

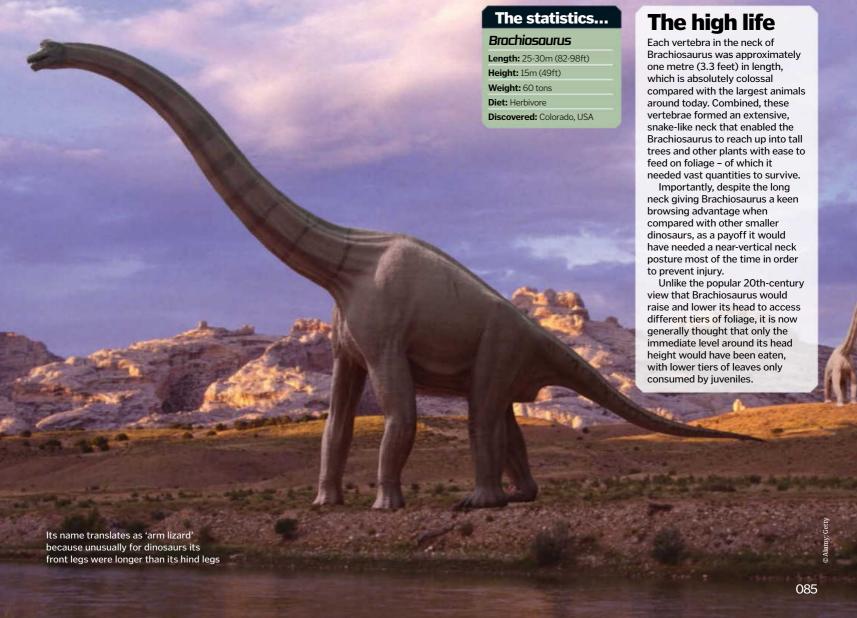

The epic size of Brachiosaurus was also its primary form of defence when it came to predators. Once fully grown, their legs would have resembled tree trunks and these – partnered with a heavy, stocky tail – made them extremely difficult to tackle.

While their size and domination granted many benefits, it was also a contributor to Brachiosaurus's eventual demise, with resource depletion and climate change leading to their background extinction around 145 million years ago.

Ankylosaurus A club-wielding brute of a creature, this tough dino had the power to break bones

supported the front half of the

animal. The wide foot area of

these forelegs granted good

traction and stability

Ankylosaurus was one of the largest ankylosaurs, a genus of armoured dinosaurs that lived throughout North

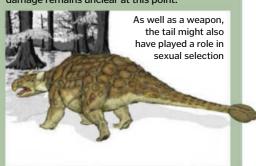

America between 75 and 65.5 million years ago. Famous for both its brutal tail-mounted club and its immense bone plate armour, the Ankylosaurus was a defensive titan, capable of fending off rivals many times its size.

Ankylosaurus's focus on defence was born out of its herbivorous nature, with its entire body geared towards the consumption of foliage. From its low-slung body, rows of leaf-shaped cropping teeth, short front legs, wide feet and cavernous stomach, the Ankylosaurus was the consummate browser, devouring vegetation whole with little shredding or chewing. Indeed, studies have indicated that the skull and jaw of the Ankylosaurus were structurally tougher than many similar, contemporary dinosaurs.

In fact, evidence suggests that Ankylosaurus - and ankylosaurs in general - were adept survivors. But despite their impressive armour, weaponry and sustainable diet, they could not cope with the Cretaceous-Tertiary extinction event that wiped out all terrestrial dinosaurs approximately 65.5 million years ago. Only a few fossils of this prehistoric herbivore have been excavated to date - most coming from the Hell Creek Formation in Montana, USA.

Club members only

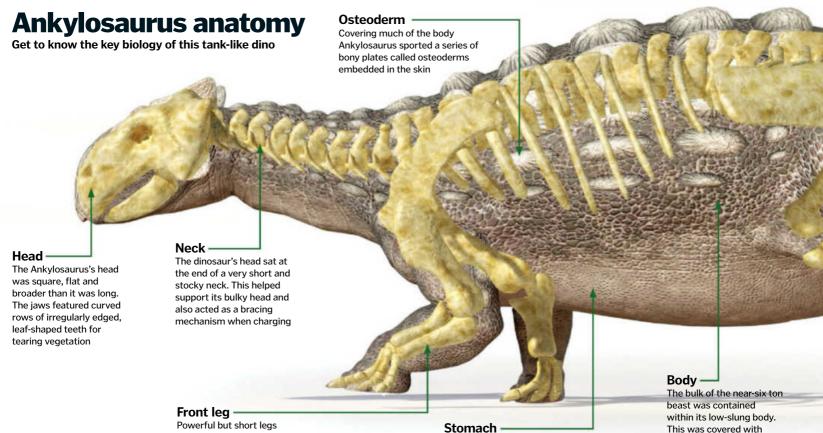

The well-known tail club of the Ankylosaurus was one of the most lethal weapons sported by any dinosaur. The club was made from several large bone plates called osteoderms that were fused into the last few vertebrae of the animal's tail. Behind these vertebrae several others lined with thick, partially ossified tendons completed the club's handle, resulting in a structure that, when swung, was capable of dealing out a lot of damage. Indeed, a study in 2009 suggested that the tail clubs of fully grown ankylosaurs could easily crush and break bone with a force capable of caving in an assailant's skull. Whether or not the animal purposely aimed the club to cause damage remains unclear at this point.

This was covered with

armoured bone plating

and topped with spines

The only part of the dinosaur

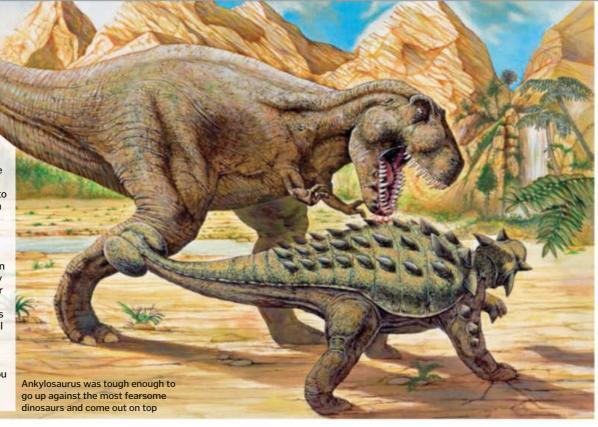

that was unarmoured, the

underbelly hung low to the

ground. Predators would try to tip Ankylosaurus over to access this weak point

You shall not pass!

The impressive, almost bulletproof armour of the Ankylosaurus was not magic but rather a series of interlocking bone plates called osteoderms. These bone plates, which were locked into the skin, were bone overlaid with a tough layer of keratin. The plates were located over most of the body, but were not uniform in shape nor size, with some resembling flat diamonds - as seen on crocodiles and armadillos today - and others appearing like circular nodules. The addition of these plates on top of the Ankylosaurus's head, along with a set of pyramidal horns to its rear and a row of triangular spikes mounted to each side of the tail club meant that attacking this creature - even if you were an apex predator like the T-rex - was not a good idea.

Spine

At key areas Ankylosaurus also sported bony spines for extra protection or – in the case of those mounted to the side of the tail club – greater offensive capabilities "Ankylosaurus's focus on defence was born out of its herbivorous nature"

Club ·

The characteristic tail club of Ankylosaurus was made from numerous osteoderms, each fused to the last few vertebrae of the tail

Tail

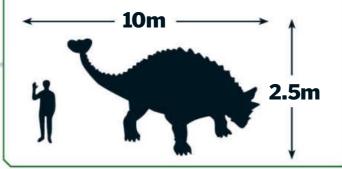

A medium-sized tail – also armoured with bone plates – helped balance the weighty Ankylosaurus and provided the power to cause maximum damage with its club

Rear leg

Equally powerful – if not more so – but longer than the Ankylosaurus's forelegs, the rear legs reached up to about 1.7m (5.6ft) at the hip

Ankylosaurus vs human

How would this dino have sized up to a person?

Alamy. Get

Apatosaurus had a deep, slender skull filled with long peg-like teeth. These broad, rounded teeth were excellent at stripping off leaves from branches

Neck

As with other sauropods, the Apatosaurus's neck vertebrae were deeply bifurcated, carrying paired spines. The neck was also filled with many weightsaving air sacs

Meet the real Brontosaurus

One of the largest animals to ever exist on Earth, the Apatosaurus towered metres over its Jurassic rivals

Around four times heavier than an African elephant, five times longer than your car and almost six times the height of a full-grown human, Apatosaurus was one of the largest dinosaurs of the Jurassic era and one of most gigantic to ever walk the Earth.

As is typical with large dinosaurs of this period, Apatosaurus (once mistakenly known as Brontosaurus) was a herbivore, consuming vast quantities of foliage and grasses over the lands that now form modern-day North America. Interestingly, despite its size, its name is derived from the Greek 'apate' and 'saurus', which translate as 'deception lizard' – a name bestowed by its original discoverer, American palaeontologist Othniel Charles Marsh.

Prior to the 1970s, Apatosaurus, along with many other sauropods, were considered largely aquatic creatures that relied on being partially submerged in swamps and lakes to remain stable – a view seemingly confirmed by their

colossal bulk. However, recent evidence has demonstrated that through a combination of massive limb bones and a series of weight-reducing internal air sacs located throughout the neck and spine, Apatosaurus's home was, in fact, entirely land-based, only spending time at water sources to drink.

Torso

A colossal torso that weighed many tonnes

organs, including a 500-litre, four-chambered

was standard containing similarly huge

heart and two 900-litre capacity lungs

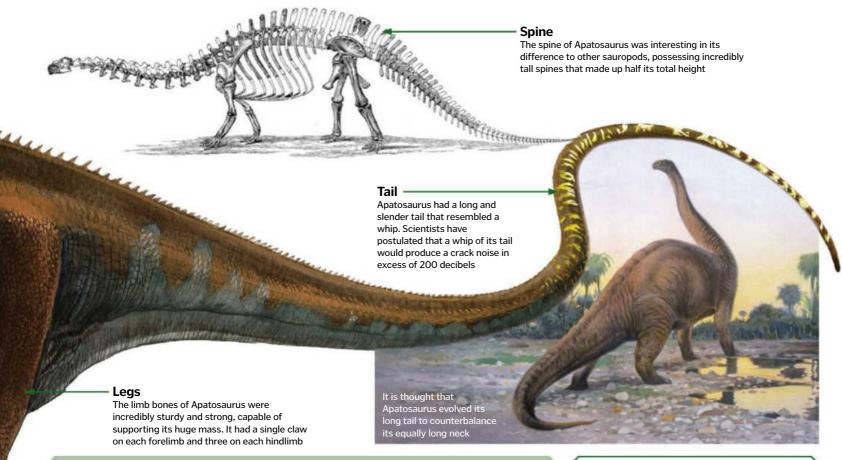

Speaking of drinking, the Apatosaurus required gallons of water per day to remain healthy, while it also needed to process vast amounts of food, spending a large proportion of each day grazing. It did this with few predators, as only the largest carnivorous dinosaurs had any chance of bringing down an Apatosaurus, largely thanks to its size. It also had a deadly weapon in its tail, which was capable of being swung at great velocity at any foes.

Despite its defensive prowess, however, the Apatosaurus could not battle off extinction, with it falling to a medium-sized extinction event around 150 million years ago.

Apatosaurus vs human How would this enormous dinosaur have sized up to a person? 23m

Apatosaurus possessed incredibly long, robust ribs compared to most other diplodocids, granting it

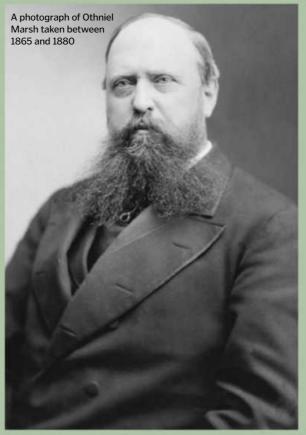

an unusually deep chest cavity

The bone wars

During the beginning of the golden age of modern palaeontology, two prominent American palaeontologists, Edward Cope and Othniel Marsh, had a falling out over excavated dinosaur remains, with the men then proceeding to attempt to beat each other to unearth and describe new species of dinosaur. In this rush to become the foremost palaeontogist of the age, Marsh described first in 1877 and then later in 1879 two supposedly separate species of dinosaur. He named the first one Apatosaurus and called the second one Brontosaurus.

Following this, the name of Brontosaurus became world famous, with a complete skeleton mounted and displayed in the Peabody Museum, Yale, under the Marsh title in 1905. However, Marsh in his haste had made a terrible mistake. The Brontosaurus was actually just a fully-grown Apatosaurus and, since the Apatosaurus had been described first in 1877, its name took precedent, with 'Brontosaurus' made officially redundant in the early-20th century. Interestingly, however, as the Brontosaurus name had become firmly fixed in the public consciousness, it remained far more popular and is still in use to this day to the chagrin of many dinosaur experts.

Stamp scandal

In 1989, the US Post Office decided to release a special edition set of four stamps depicting famous dinosaurs. These included a Tyrannosaurus, Stegosaurus, Pteranodon and, interestingly, a Brontosaurus.

The latter was included despite the fact that, as noted in 'The bone wars' boxout, the name 'Brontosaurus' had been made officially redundant in the early-20th century.

The fallout from this was massive, with many palaeontologists and dinosaur enthusiasts accusing the US Post Office of promoting 'scientific illiteracy' and re-opened a bone war-style feud between others. Indeed, even the celebrated palaeontologist Stephen Jay Gould got involved, writing a famous defence of the Brontosaurus name in his Natural History magazine piece 'Bully for Brontosaurus'.

Marine reptiles

Discover the creatures that ruled and dominated the prehistoric waters

Plesiosaurs

These powerful reptiles were every inch the aquatic version of a dinosaur

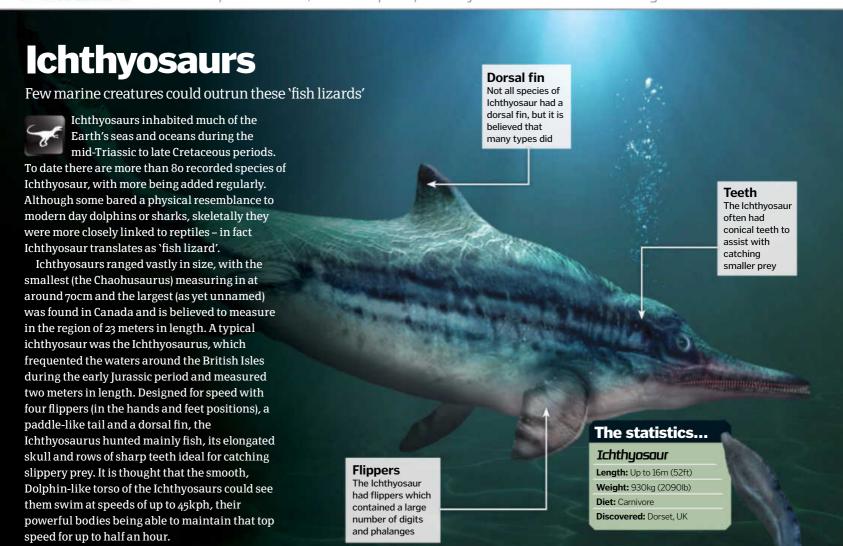

Plesiosaurs were part of marine ecology from the late Triassic period to the end of the Cretaceous period and were powerful swimmers that could strik

and were powerful swimmers that could strike fast-moving prey with efficiency. Plesiosaurs typically had a stocky torso, four large flippers, a long neck and a small skull with small, pointed teeth and one such example was the

Plesiosaurus, which inhabited the shallow seas of Europe during the early Jurassic period.

Measuring anywhere between 3-5 meters in length, the Plesiosaurus was one of the very first prehistoric reptiles to be discovered and the fossil remains pointed very much towards a powerful creature that was build to cope with its precise fish-catching feeding habits. With a

forward burst of the flippers on one side of its body coupled with backwards thrust of the flippers on the other side could turn the Plesiosaurus on a sixpence, its relatively weak, stumpy tail acting as a rudder to steer it. It was such agility that the helped the plesiosaurs dominate the ecosystem as no unsuspecting fish would have been able to escape it.

Mosasaurs

Introducing the T-Rex of the seas...

Mosasaurs lived in the late Cretaceous

period and were the true giants of the sea. Some mosasaurs, such as the Hainosaurus, could reach lengths of up to 17 meters, their huge frames typically spent swimming slowly along the sea beds stalking slow-moving prey such as ammonites and turtles. However, as mosasaurs could breathe air, seabirds were also part of their ecosystem. Possessing two sets of conical teeth, mosasaurs used rocks and underwater plantation as cover to close in on their prey and then strike quickly. Some skeletal remains indicate that they were susceptible to attacks by shark-like predators.

The first mosasaur remains were uncovered around the 1770s in an underground mine near Maastricht, Holland, on the Meuse River. Fossil skin impressions indicate that they possessed scaly skin similar to that of a snake.

Snake-like In 1869 it was suggested Most mosasaurs had a that mosasaurs shared double jaw which allowed common ancestry with The statistics... them to eat their prey in snakes, who coined the one go term Pythonomorpha to Mosasaur unite them Length: Up to 17m (56ft) Weight: Up to 20 tonnes Diet: Carnivore Discovered: Maastricht, **Eating habits** The larger mosasaurs were the kings of the Late Cretaceous seas, feeding on fish and ammonites

Plesiosaurus

We turn the spotlight on a ferocious marine reptile that dominated Earth's oceans throughout the Early Jurassic

Streamlined

A muscular torso allows for great propulsion

The statistics...

Plesiosaurus

Length: 4.5m (15ft)

Neck vertebrae: 40

Weight: 90kg (200lb)

Diet: Carnivore; eg fish, squid

Discovered: Dorset, UK

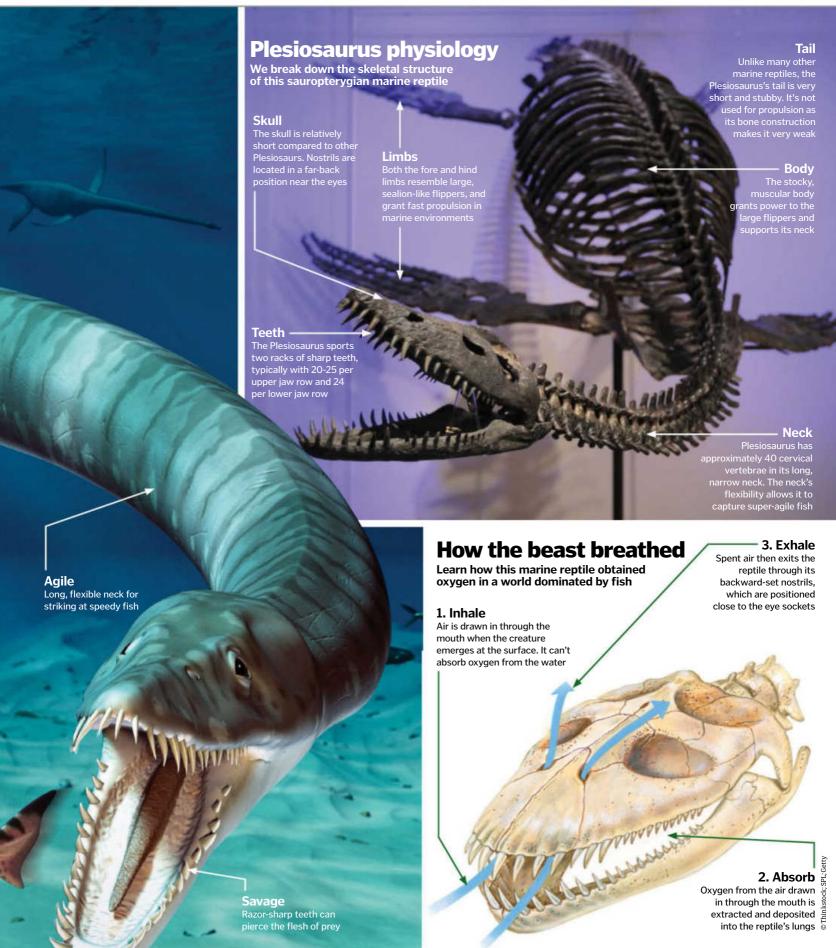

Plesiosaurus was an unusual long-necked marine reptile that lived in the Early Jurassic period (circa 199-175 million years ago).

This member of the sauropterygian superorder measured in at approximately 4.5 metres (15 feet) in length, sported a muscular and stocky body, a long and narrow neck, plus a short, stubby tail. Four large flipper-like limbs that attached in pairs to the torso allowed the creature to propel itself through the water at great speed, while a small head packed with rows of sharp, curved teeth ensured that once it got hold of its dinner there was no getting away.

Despite the reptile's underwater dominance, the Plesiosaurus could not in fact breathe underwater like fish so had to surface to draw in air. Due to its size, however, it could spend a considerable length of time submerged, allowing it to repeatedly dart through shoals of fish and squid while hunting.

Plesiosaurus inhabited the shallow seas of what is now Europe, dominating the waters due to its size, agility and ferocity. Early in their history, this domination reached new heights when the order split-evolved into two main lineages: Pliosaurs and Plesiosaurids. The former developed a shorter neck and elongated head, while the latter developed a snake-like neck of epic proportions. This divergence allowed the species in each lineage to prey on an increasingly varied range of creatures, with some giants, such as Pliosaurus funkei (formerly 'Predator X'), even capable of attacking other Plesiosaurs.

Plesiosaurus became extinct at the opening of the Middle Jurassic period (175 MYA), being superseded by its larger, more dominant relatives, like the Elasmosaurus. The Plesiosauria order, however, survived much longer, thriving worldwide until the Cretaceous-Tertiary (K-T) extinction event.

Fly away The discovery of embryo pterosaurs has lead scientists to believe they could fly from birth due to well-deveoped wing membrane

Discovery

The first pterosaur was discovered by Italian naturalist Cosimo naturalist Cosimo Alessandro Collini in 1784

Pterosaurs

Whatever you do, don't call them 'flying dinosaurs'

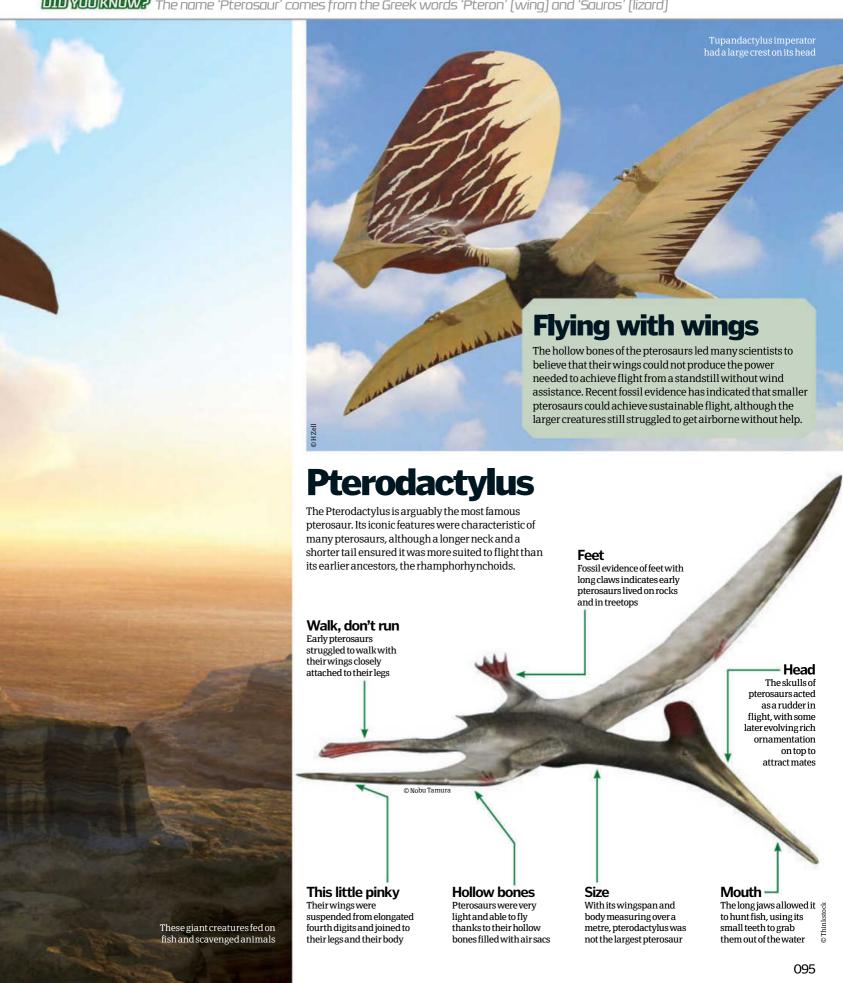

These flying reptiles lived alongside dinosaurs in a variety of environments across the Earth from the Late Triassic to the end of the Cretaceous period (225 to 65 million years ago). They ranged in size from just a few centimetres to more than 12 metres (one inch-39 feet), mostly feeding on fish while some scavenged dead animals and ate insects inland.

The wing of the pterosaur was unique, a large membrane suspended from a hugely expanded fourth finger. Pterosaurs are largely regarded as the first vertebrates to achieve sustainable powered flight, although the largest relied mainly on the wind and gliding to stay in the air. There is much contention among palaeontologists as to whether these flying reptiles should be classed as dinosaurs, but the

physical similarities are plain to see nonetheless, which is why we have included them here.

The Quetzalcoatlus is the largest of the pterosaursin fact it is the largest known flying animal of all time. With a wingspan of up to 12m (39 feet) and a head the size of a car, the Quetzalcoatlus ruled the sky in the Late Cretaceous period (100 to 65 million years ago). It is widely believed that Quetzalcoatlus fed on living dinosaurs, unlike other pterosaurs who preferred fish and dead animals, to fuel its enormous metabolic needs. Despite its incredible size this giant reptile weighed no more than 250kg (550lb) due to the hollow bones associated with pterosaurs.

Pterosaurs faced extinction after more than 150 million years at the same time as the dinosaurs, conquering every single continent in the process.

Quetzalcoatlus

Discover more about the mysterious serpent of the sky and the largest flying vertebrate of all time

Not a great deal is actually known about this pterosaur that dates back to the late

Cretaceous period, as only fragments have ever been discovered. However, evidence suggests that the Quetzalcoatlus possibly boasted a wingspan of up to 12m – making it the largest flying vertebrate of all time. But, despite its colossal size, its weight has been suggested could have been as low as 190lbs, but certainly no more than 550lbs. This was perhaps down to a complex system of air sacs situated inside many of the creature's bones that kept its weight down so as to be able to stay airborne for longer.

The Quetzalcoatlus's long, narrow wings made it an excellent glider, and while initial reports suggested that it could have used this skill to hover over water and scour the oceans for prey, it is now believed that it lived

inland. The Quetzalcoatlus would have used rising thermals to glide high above the land, its keen eyes spotting prey from long distances like a modern day vulture – prey that consisted of vertebrates of all sizes. Thanks to its long neck and sharp, toothless jaws, the Quetzalcoatlus would have been able to probe deep inside large carcasses to devour the contents in order to fuel its gigantic metabolic requirements.

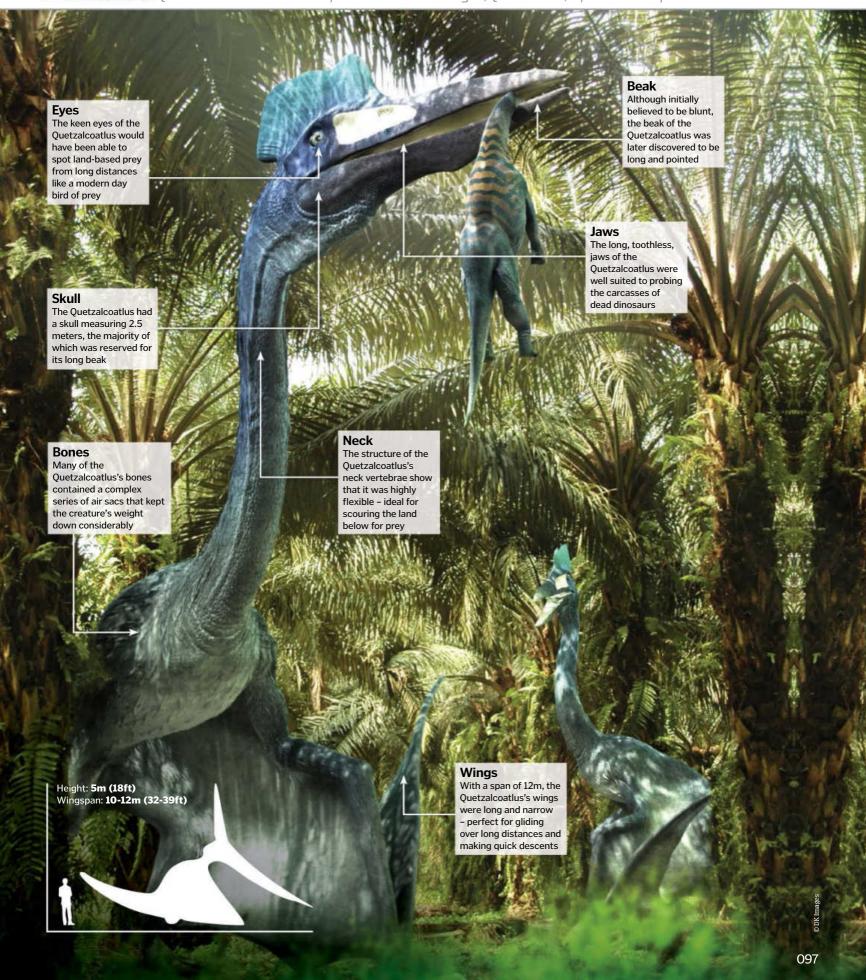

So far, fragments of the Quetzalcoatlus have only been found in Texas, North America, but it would be safe to assume that they were well equipped to traverse far further afield. Putting things into perspective, the next flying reptile down on the size scale, the Pteranodon, boasted a wingspan of 7m, a whole five meters shy of the Quetzalcoatlus (whose span would dwarf many small planes). More

extensive remains of Pteranodons have been found as far afield as Europe and North America (England and Kansas, to be precise).

So while not as famous as some of the other species of winged reptiles, Quetzalcoatlus has emerged to be something of a winged wonder amongst the pterosaurs. A creature that steered a course inland away from its sea-scouting Pteranodon peers (the fragment remains were discovered about 400 kilometers inland from the nearest coastline and away from any large rivers or lakes present in the area during the Cretaceous period) to survive on a diet of small vertebrates and the discarded remains of other larger dinosaurs. And with new theories emerging regularly as to how the creature lived, it appears that the Quetzalcoatlus isn't quite ready to give up all of its secrets yet.

staggering seven tonnes (15,400 pounds), the T-rex was once thought to have been the largest terrestrial carnivore in history, but subsequent discoveries of fellow titans Carcharodontosaurus, Giganotosaurus and Spinosaurus challenged this.

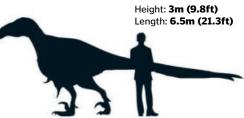

The T-rex walked on a pair of powerful hind legs and could run as fast as a professional footballer, but balance issues meant that

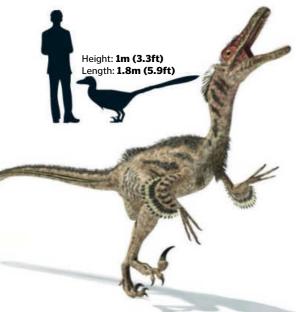

scavenge. And then there is its not-so-secret weapon: its phenomenal bite, which was stronger than that of any land animal that ever lived. Its bone-splintering jaws chomped down with a force almost as huge as its own body weight, bringing to bear its 60 saw-edged conical teeth. Other dinosaurs had to close their mouth around prey multiple times to bring it down; T-rex only had to bite once.

Utahraptor

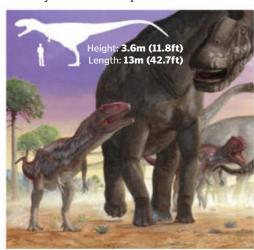

The mighty Utahraptor ("YOU-tah-RAP-tor") was three times larger and meaner than its cousin, the Velociraptor. Armed with a 30-centimetre (12-inch)-long sickle-shaped claw on each hind foot, it would kick, rip and tear its prey to death. Its leg bones were unusually thick, in order to support the powerful muscles dedicated to repeatedly driving the killing claw into its prey. In keeping with its smaller raptor cousins, it's possible that Utahraptor hunted in packs, like terrible three-metre (9.8-foot)-tall 500-kilogram (1,100-pound) wolves, and targeted prey many times larger than itself.

Velociraptor

Star of the infamous kitchen scene in *Jurassic Park*, the curious creature with the deadly curved toe claw has been terrorising nightmares for two decades. The film may have overstated their size and stripped them of their feathers, but it did get some things right: Velociraptors ("vel-OSS-e-RAP-tors") were fast and polished predators that oozed agility and intelligence, and may have hunted in packs.

Mapusaurus

A close cousin and look-alike of Giganotosarus, Mapusaurus ("MAH-puh-SORE-uss") hunted some of the largest dinosaurs that ever lived – the 35-metre (115-foot)-long herbivore Argentinosaurus. Its narrow blade-like teeth were ideal slicing tools, and the discovery of bones from several individuals found in one place has experts speculating that they formed groups or hunted in packs for extra lethality.

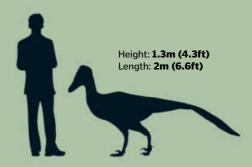

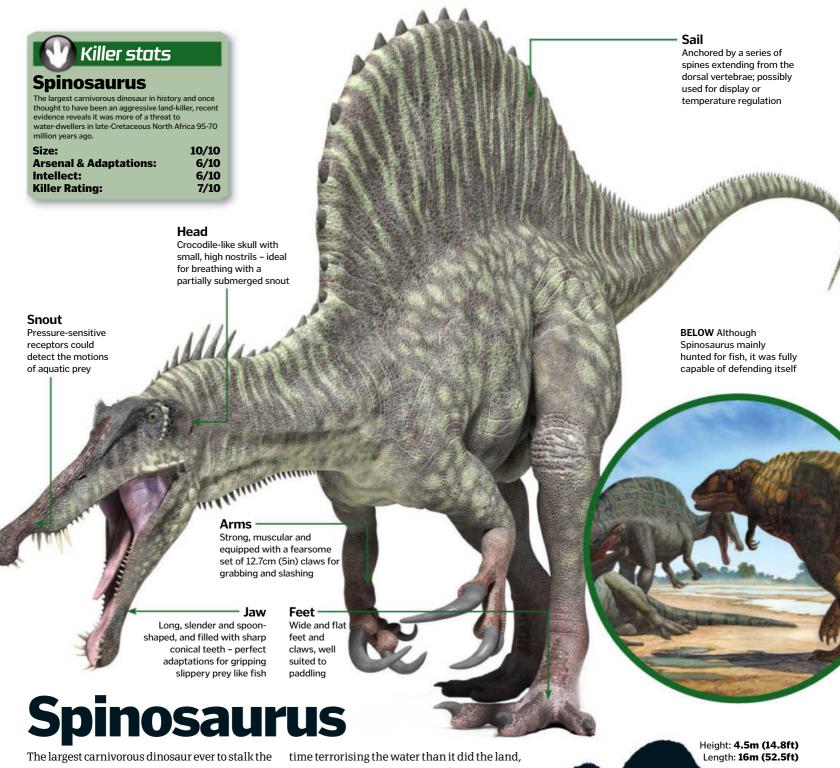

Troodon

Deadliness doesn't always come down to bulk and bite force. Troodon ("TROH-oh-don") – standing just 1.3 metres (4.3 feet) tall and weighing in at 40 kilograms (88 pounds) – was a wily whippet that made up for its lack of brawn with a whole lot of brain. In fact, it had the highest brain-to-body-weight ratio of any known dinosaur. Not only that; reconstructions of its brain have revealed nascent signs of folding – where more neural cells are packed into the same area for more efficient brain functioning – making it the most neurologically advanced specimen too.

The shape of fossilised skull remains suggest it possessed huge orb-like eyes that gave it superior vision – as well as the ability to see in low-lighting

conditions and hunt nocturnally – and its slight frame made it extremely fleet of foot. While they may have been dwarfed by many of the behemoths on this list, a pack of alert and agile Troodons hunting as a pack could easily have brought down much bigger animals.

The largest carnivorous dinosaur ever to stalk the Earth, Spinosaurus is thought to have been as long as one and a half double-decker London buses – 16 metres (52.5 feet) – and as heavy as a herd of Asian elephants (20 tonnes). Its vertebrae were 20 per cent larger than those of T-rex and to top it off, it sported a gigantic sail of skin supported by two-metre (6.6-foot)-long spines protruding from its back.

Despite its imposing physique, recent evidence suggests Spinosaurus spent more of its

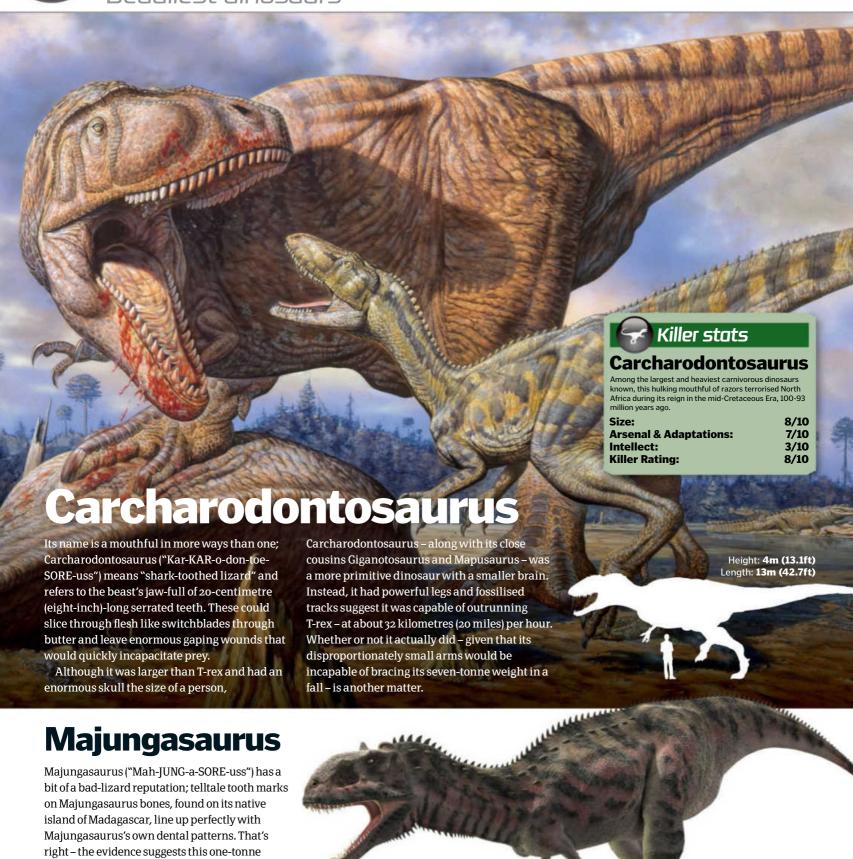

time terrorising the water than it did the land, and would only supplement its fishy diet with scavenged carrion. Its crocodile-like jaw had smooth, conical, pointed teeth, well adapted to spearing slippery prey like Onchopristis – eightmetre (26-foot)-long prehistoric sawfish – rather than ripping flesh from bone. Special structures in its snout helped it detect pressure waves caused by prey moving in the water.

Nevertheless, Spinosaurus was fast, strong and possessed a cruel set of claws, meaning it

Height: 4.5m (14.8ft) Length: 16m (52.5ft)

could likely hold its own against other massive predators, like Carcharodontosaurus, who shared its territory. Despite what you might think, they never came up against the T-rex.

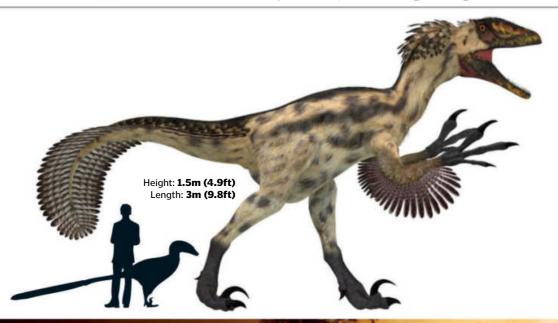

Height: 2m (6.6ft)

Length: 6m (19.7ft)

theropod feasted on its own kin, at least occasionally – surely the hallmark of a ruthless killer? What isn't known, though, is whether these were the spoils of active hunts or just

efficient tidying up of already-dead relatives.

Deinonychus

The discovery of Deinonychus ("Dee-NON-i-KUSS") in 1964 overhauled our perception of dinosaurs as languid and lumbering; here was a creature clearly built for speedy pursuit. Almost twice the size of Velociraptor (insider tip – the 'Velociraptors' in Jurassic Park were actually modelled after the bigger, badder Deinonychus!), but a similar weight, it was a sprightly and most likely a quick-witted pack hunter. Among other advantages, it possessed interlocking vertebrae that allowed its tail to stiffen for balance when running, and a retractable 13-centimetre (five-inch) claw on each foot to disembowel prey restrained in its hands and jaw.

Giganotosaurus

Carcharodontosaurus's South American cousin, Giganotosaurus ("GIG-a-NOTE-o-SORE-uss") was another beast to rival T-rex for size. Depending on the specimen, it is thought to have been slightly smaller than Carcharodontosaurus, but longer, taller and more slender than T-rex. It was the fastest of the three, besting the others by at least 16 kilometres (ten miles) per hour, perhaps thanks to its superior balance.

It had a very large skull but, like
Carcharodontosaurus, it was more
neurologically primitive than T-rex; its brain
was a puny half the size of T-rex's. Still, evidence
suggests it had a keen sense of smell, which
coupled with its athletic prowess and eighttonne bulk made it a formidable foe.

Like Carcharodontosaurus, Giganotosaurus's teeth were serrated and laterally compressed – wide in profile but narrow when viewed from the front – making them ideal tools to deliver a series of injurious slices to the body of its prey, which would eventually keel over from exhaustion and blood loss.

Olfactory system

Large nostrils and advanced olfactory bulbs in its small brain gave it a keen sense of smell for hunting down prey

Bite

Height: 4m (13.1ft)

Length: 12.5m (41ft)

Although Giganotosaurus's jaw was only a third as powerful as T-rex's, it was packed with sharp, serrated 20cm (8in) daggers

Tail

Thin and pointed, it gave Giganotosaurus the ability make quick turns at top speeds without toppling over

Leas

Long and strong legs meant this killer could easily outsprint T-rex at an estimated 50kmh (31mph)

Killer stats

Could dinos fly?

The death of the dinosaurs

Loads of theories surround the death of the dinosaurs, we get to the bottom of it

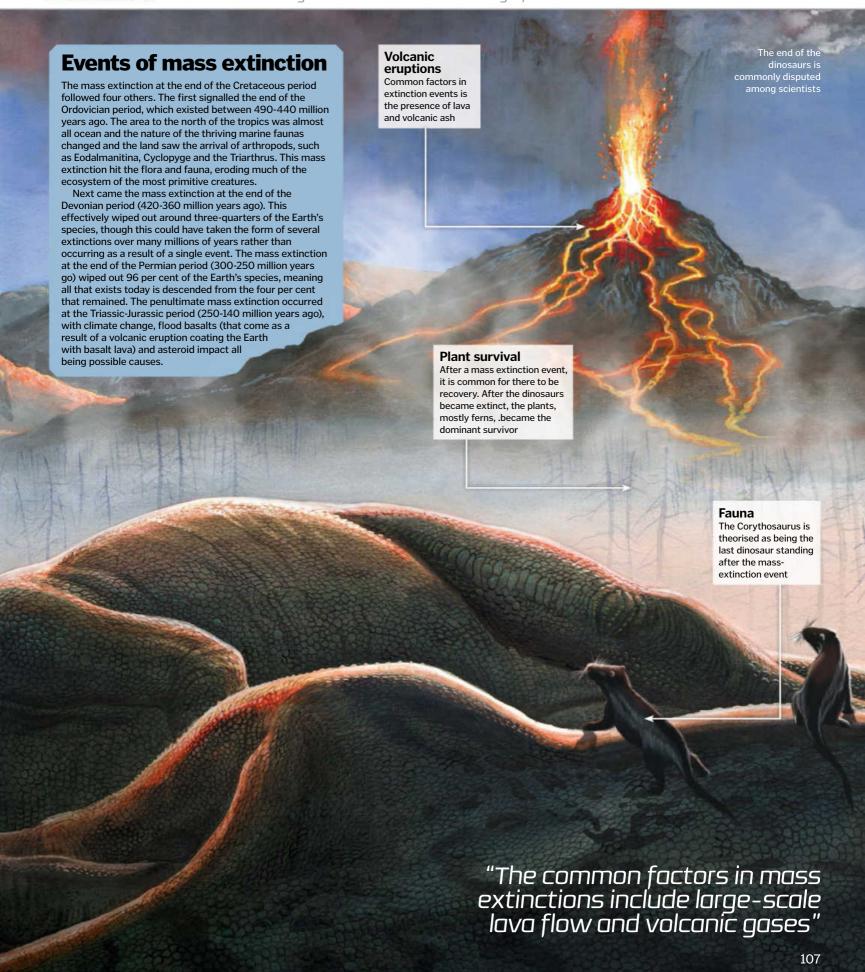

It is believed that there have been at least five mass extinctions in the last 540 million years, the most famous being the one that signalled the end of the Cretaceous period around 65.5 million years ago and effectively wiped out the dinosaurs.

Palaeontologists initially believed that this mass extinction event was caused by climate and geological changes. This theory changed in the 1980s when scientists Luis and Walter Alvarez discovered a layer of iridium in the geological record that corresponds with the time that the dinosaurs became extinct. This substance existed only in space and so its presence on Earth must have come as a result of

a comet, asteroid or meteor colliding with Earth. The discovery of the colossal Chicxulub are followed by recovery. Following the events Crater in Mexico's Yucatán Peninsula that dates of the Cretaceous period that rendered the back to the time of the mass extinction adds significant weight to this theory.

As a result, the Earth suffered a series of volcanic eruptions. Research has shown that the common factors in mass extinctions include large-scale lava flow and volcanic gases, which desecrate the land and suck all of the oxygen out of our oceans. The gases coughed out of volcanic eruptions, most notably carbon dioxide, are linked to short-term regional warming, acid rain and ozone depletion - the perfect cocktail to snuff out any creature.

Based on the fossil record, mass extinctions dinosaurs extinct, the gradual recovery of vegetation was evident by the discovery of fern spores. Plants managed to adapt to cope with conditions on Earth. The fossil record tells us that the last dinosaur to walk the Earth was the Corythosaurus. This herbivore stood upright, with two arms used to strip and devour vegetation and was easily identifiable by a decorative semicircular crest on its head. Much effort has been spent searching for the causes of mass extinctions because ultimately there is no reason why another couldn't occur again.

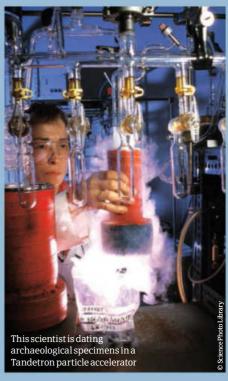

Carbon dating

A crucial tool for palaeontologists, carbon dating allows ancient fossils to be accurately dated

Carbon dating is a method of radioactive dating used by palaeontologists that utilises the radioactive isotope carbon-14 to determine the time since it died and was fossilised. When an organism dies it stops replacing carbon-14, which is present in every carbonaceous organism on Earth, leaving the existing carbon-14 to decay. Carbon-14 has a half-life (the time it takes a decaying object to decrease in radioactivity by 50 per cent) of 5,730 years, so by measuring the decayed levels of carbon-14 in a fossil, its time of death can be extrapolated and its geological age determined.

e

The origin of life on Earth is irrevocably trapped in deep time. The epic, fluid and countless beginnings, evolutions and

extinctions are immeasurable to humankind; our chronology is fractured, the picture is incomplete. For while the diversity of life on Earth today is awe-inspiring, with animals living within the most extreme environments imaginable – environments we as humans brave every day in a effort to chart and understand where life begins and ends – it is but only a fraction of the total life Earth has seen inhabit it over geological time. Driven by the harsh realities of an ever-changing environment, Armageddon-level extinction events and the perpetual, everpresent force of natural selection, wondrous creatures with five eyes, fierce predators with 12-inch fangs and massive creatures twice the size of

a double-decker bus have long since ceased to exist. They are forgotten, buried by not just millions, but billions of years. Still, all is not lost to us. By exploiting Earth's natural processes and modern technology over the last two hundred years, scientists and palaeontologists have begun to

but, in general, it occurs when a recently deceased creature is rapidly buried by sediment or subsumed in an oxygen-deficient liquid. This has the effect of preserving parts of the creature – usually the harder, solid parts like its skeleton – often in the original, living form within the Earth's crust. The softer parts

"The softer parts of fossilised creatures tend not to survive due to the rapidity of decay"

unravel Earth's tree of life and, through the discovery and excavation of fossils – preserved remains and traces of past life in Earth's crust – piece the jigsaw back together.

The fossilisation of an animal can occur in a variety of ways (see 'Types of fossilisation' boxout)

of fossilised creatures tend not to survive due to the speed of decay and their replacement by minerals contained in their sediment or liquid casing, a process that can leave casings and impressions of the animal that once lived, but not its remains. Importantly, however, creature fossilisation tends to

be specific to the environmental conditions in which it lived – and these in themselves are indicative of certain time periods in Earth's geological history. For example, certain species of trilobite (an extinct marine arthropod) are only found in certain rock strata (layers of sedimentary and igneous rocks formed through mineral deposition over millions of years), which itself is identifiable by its materials and mineralogic composition. This allows palaeontologists to extrapolate the environmental conditions (hot, cold, dry, wet, etc) that the animal lived and died in and, in partnership with radiometric dating, assign a date to the fossil and/or the period.

Interestingly, however, by studying the strata and the contained fossils over multiple layers, through a mixture of this form of palaeontology and phylogenetics (the study of evolutionary relatedness between organism groups), scientists can chart the evolution of animals over geological time scales. A good example of this process is the now known transition of certain species of dinosaur into birds. Here, by dating and analysing specimens such as archaeopteryx - a famous dinosaur/bird transition fossil - both by strata and by radiometric methods, as well as recording their molecular and morphological data, scientists can then chart its progress through strata layers to the present day. In addition, by following the fossil record in this way, palaeontologists can also attribute the geophysical/chemical changes to the rise, fall or transition of any one animal/plant group, reading the sediment's composition and structural data. For example, the Cretaceous-Tertiary extinction event is identified in sedimentary strata by a sharp decline in species' diversitynotably non-avian dinosaurs – and increased calcium deposits from dead plants and plankton.

Excavating any discovered fossil in order to date and analyse it is a challenging, time-consuming process, which requires special $\,$ tools and equipment. These include picks and shovels, trowels, whisks, hammers, dental drills and even explosives. There is also an accepted academic method all professional palaeontologists follow when preparing, removing and transporting any discovered fossil. First, the fossil is partially freed from the sedimentary matrix it is encased in and labelled, photographed and reported. Next, the overlying rock (commonly referred to as the 'overburden') is removed using large tools up to a distance of two to three inches from the fossil, before it is once again photographed. Then, depending on the stability of the fossil, it is coated with a thin glue via brush or aerosol in order to strengthen its structure, before being wrapped in a series of paper, bubble wrap and Hessian cloth. Finally, it is transported to the laboratory.

The fossil record

By examining discovered fossils, it is possible to piece together a rough history of the development of life on Earth over a geological timescale

The first geological period of the Paleozoic era, the Cambrian is unique in its high proportion of sedimentary layers and, consequently, adpression fossils. The Burgess Shale Formation, a notable fossil field dating from the Cambrian, has revealed many fossils including the genus opabinia, a five-eyed ocean crawler.

11 | ORDOVICIAN | 488.3-443.7 Ma

Boasting the highest sea levels on the Palaezoic era, the Ordovician saw the proliferation of planktonics, brachiopods and cephalopods. Nautiloids, suspension feeders, are among the largest creatures from this period to be discovered.

A Lanopasan us fossil is examined

10 | SILURIAN | 443.7-416 Ma

With its base set at major extinction event at the end of the Ordovician, the silurian fossils found differ markedly from those that pre-date the period. Notable life developments include the first bony fish, and organisms with moveable jaws.

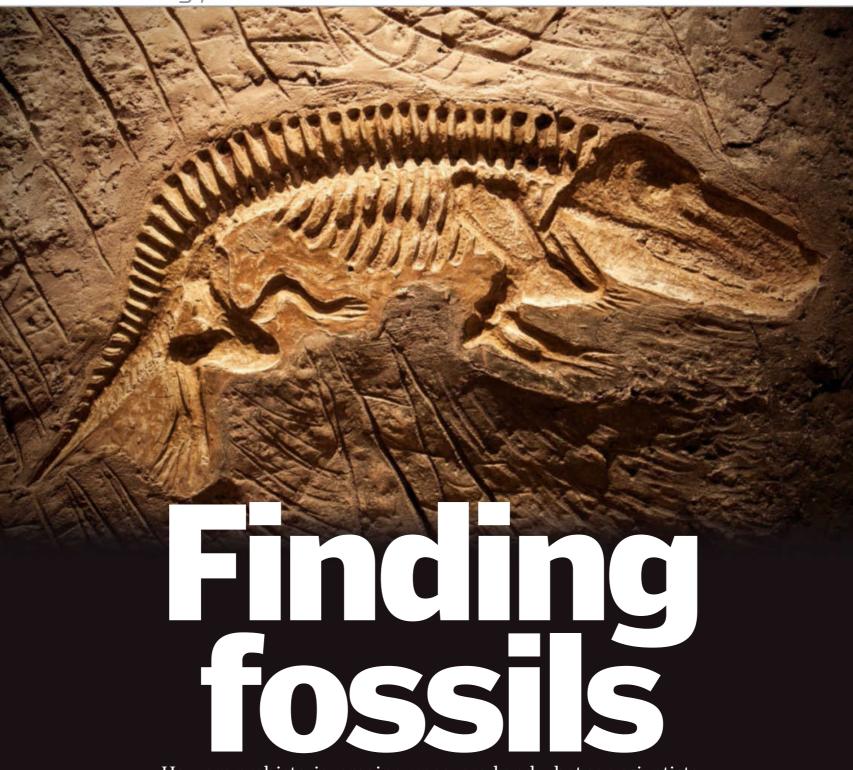

9 | DEVONIAN | 416-359.2 Ma

An incredibly important time for the development of life, the Devonian period has relinquished fossils demonstrating the evolution of the pectoral and pelvic fins of fish into legs. The first land-based creatures, tetrapods and arthopods, become entrenched and seed-bearing plants spread across dry lands. A notable Devonian find is the genus tiktaalik.

How are prehistoric remains uncovered and what can scientists learn from them? Let us dig up the facts...

Ever since Mary Anning first began piecing together the fossils of Jurassic beasts in the early nineteenth century, scientists have been learning more and more about the dinosaurs that ruled the world millions of years ago. Buried deep beneath the ground for aeons, the remains of countless extinct creatures

are waiting to be unearthed by palaeontologists, who can gradually unlock their secrets.

Dinosaurs and other prehistoric fossils have been discovered around the world for thousands of years, with reports of 'dragon bones' found in China more likely indicating some of the earliest dino finds. However, it wasn't until the brilliant scientists of the Enlightenment in the late-18th and early-19th centuries that it became clear just how old these ancient skeletons really were. Before long, fossil hunting became an obsession for naturalists and amateurs alike, with the strange extinct 'lizards' being discovered at sites all over the globe.

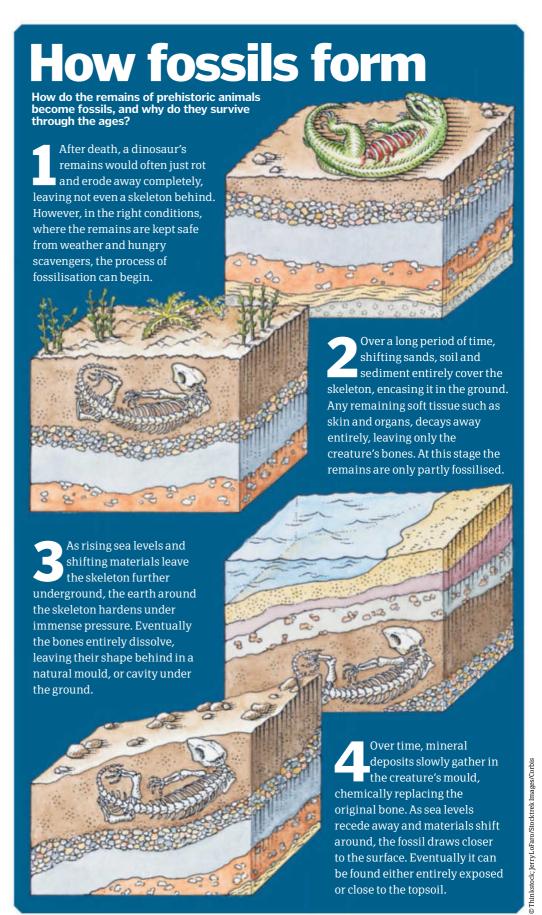

Though ground-penetrating radar now helps archaeologists identify hidden underground remains, modern palaeontologists still often rely on the same methods their 19th-century predecessors did: plain luck. Of course, through a greater understanding of geology, as well as by searching in so-called fossil hotspots, it's possible to predict where fossils will likely be found. Once a fossil site has been identified, the long and delicate process of unearthing the dino remains begins.

Digging for fossils can be as simple as sieving through sand and silt in the search for tiny teeth, or cracking open large rocks with a hammer and chisel to see what may be lying within. Hills, quarries, mountainsides and ravines are often prime locations for fossil finds, as the deep layers of rock have become exposed by millions of years of erosion. In these cases heavy diggers and drills are crucial to reach the finds. Dozens of scientists, students and even enthusiastic volunteers are employed with brushes and trowels during the course of an excavation. However, because of the delicate nature of specimens that are millions of years old, it can often take what must seem like another million to safely uproot an entire dinosaur skeleton.

Of course, palaeontologists do much more than just dig up old bones. Mixing together the disciplines of geology and biology, palaeontology is the study of fossils to reveal the history of life on Earth. So, once the fossilised remains have been fully excavated, the real work can begin back in the lab. Here scientists painstakingly remove any residual earth and stone from the specimens in preparation for full analysis. Electron microscopes, CAT scanners and X-ray machines are all employed to gather as much information about the creature as possible.

By studying the shape, length and arrangement of each fossilised bone, palaeontologists have been able to determine not only what certain dinosaurs looked like and how they moved, but also what they ate. The discovery of indentations on fossilised arm bones similar to those found on modern birds has also indicated that many species of dinosaur were actually feathered.

Bigger, stranger and ever-more unbelievable dino discoveries are being made all the time, each one challenging past theories and shedding new light on the distant land of the Mesozoic beasts. Thanks to the pioneering work of the scientists and enthusiasts of the past, each new fossil found could slot yet another piece of the prehistoric jigsaw into place.

Digging for dinosaurs

How palaeontologists discover and unearth prehistoric giants

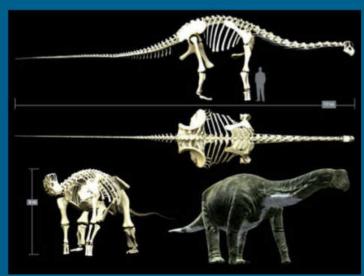

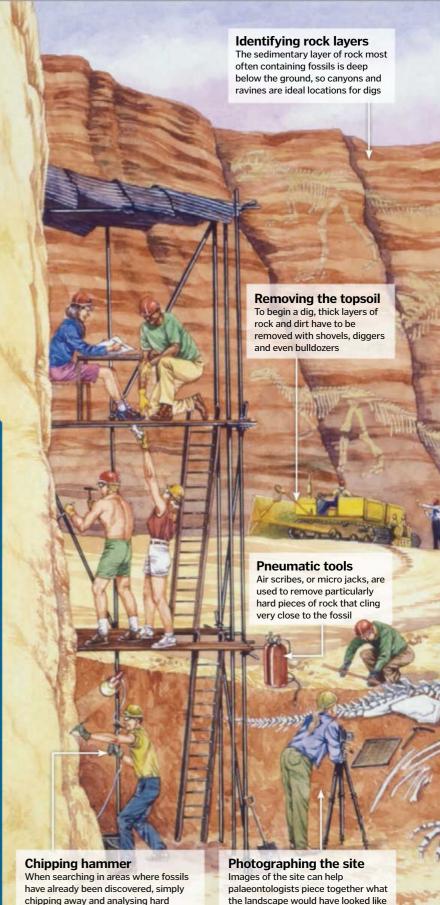

Bulldozers, hammers, chisels, drills and even dynamite – you'd be forgiven for thinking these were part of a construction-site inventory. In fact, they are the basic tools a palaeontologist will use to uncover the mysteries of the past. From removing tons of topsoil with diggers and other heavy machinery, to carefully clearing away clinging dust and debris with delicate brushes, the process of excavating a dinosaur skeleton can take many years.

The largest dino fossil

Even in this ancient time when giants ruled the Earth, sky and sea, Dreadnoughtus schrani truly was a behemoth of a creature. Standing over two-storeys tall and weighing as much 60 tonnes, the remains of this beast were found by a team in Patagonia, Argentina, and have been dated back over 77 million years. A member of the titanosaur sauropod group of dinosaurs, Dreadnoughtus was a plant-eater and is to date the largest known land animal ever to have lived.

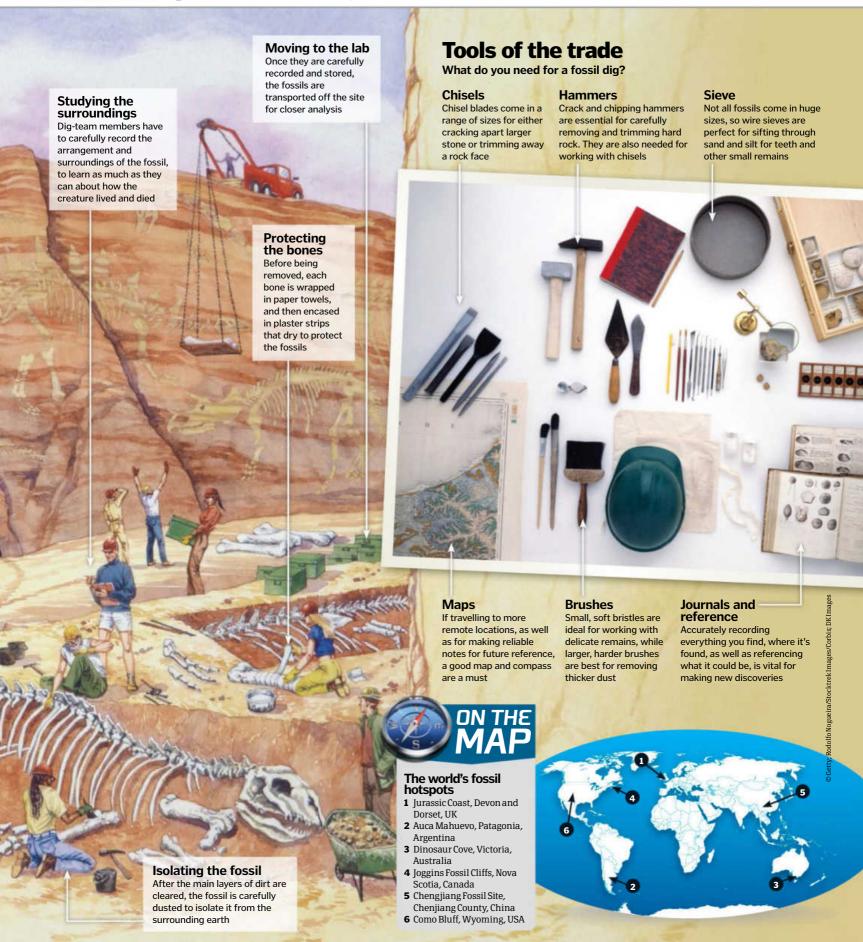

Two Dreadnoughtus titanosaurs were found at the site, and it's believed the pair died in a massive flash flood, which would explain why their remains were so complete. The preservation of the skeletons enabled scientists to take full advantage of 3D-printing technology, scanning in each individual bone into a digital format for even greater scrutiny. This 3D rendering of Dreadnoughtus provided even greater insight into how it likely looked and moved.

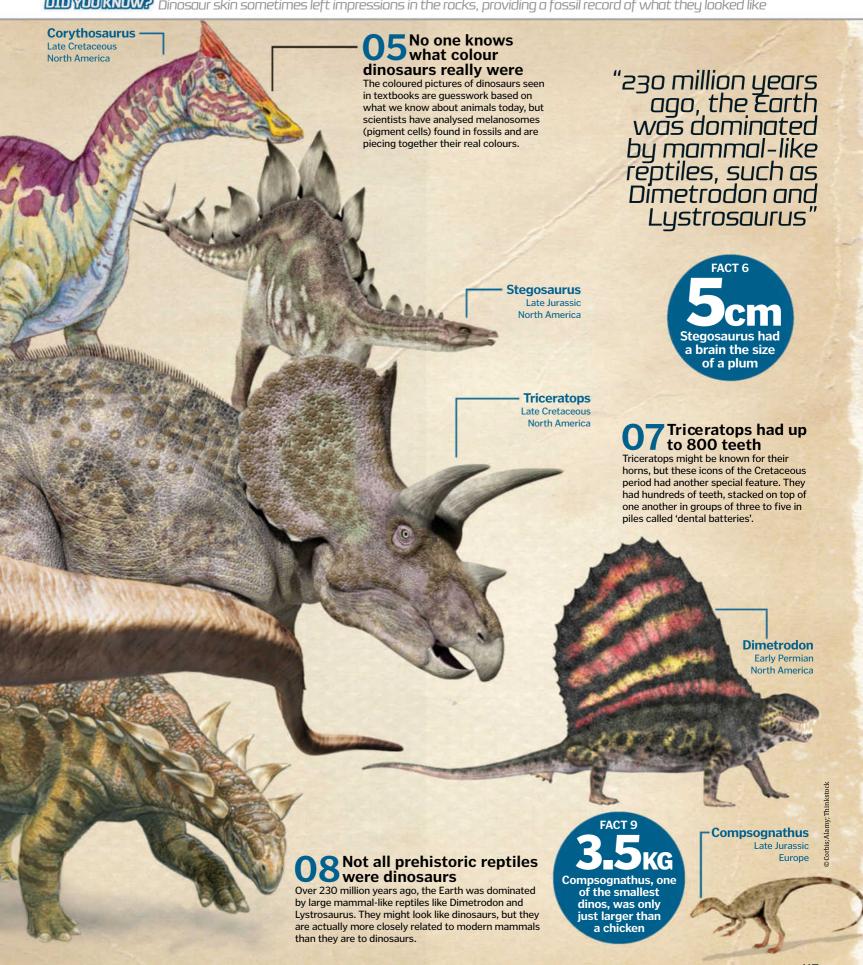

when the creature was alive

stone could unearth a new find

Sauropods These long-necked giants are among the largest animals to have ever lived

OSauropods were huge herbivores

The four-legged dinosaurs with long tails and necks are known as sauropods. The most common were Diplodocus and Camarasaurus.

Diplodocus had 15 vertebrae in its neck

At least, we think it did - there are very few complete specimens. For comparison, a human has seven neck vertebrae.

Aegyptosaurus

2Sauropods did not live in water
Early ideas about how sauropods like Diplodocus lived portrayed them walking underwater like hippos. They had nostrils on the top of their heads, and scientists thought they would use their necks like snorkels. However, with large bodies, the crushing weight of water would have prevented them from breathing, and we now know they lived on land.

Titanosaurs laid the largest eggs

The larger an egg is, the thicker its shell has to be. Even the monstrous titanosaurs had to lay relatively small eggs so that oxygen and carbon dioxide could cross over the walls of the shell.

FACT 14

Diplodocus was the length of three buses

5 You can tell if a dinosaur was female by looking at her bones

Medullary bone lines the inside of bones and stores calcium to make eggshells. It forms in female birds, its presence in fossils can also reveal the sex.

Pachycephalosaurus

Late Cretaceous North America

Charonosaurus Late Cretaceous

Hadrosaurs had duck-like bills

Hadrosaurs were the first dinosaurs found in North America, and since the nineteenth century, hundreds have been unearthed. These herbivores had a very distinctive appearance, with duck-like beaks adapted for clipping vegetation, and crested heads that might have helped to transmit sounds over long distances.

Struthiomimus Late Cretaceous North America

30rnithomimids looked and lived like ostriches

Ornithomimid means 'bird mimic', and these two-legged dinosaurs really do look familiar. They had long, muscular legs, large, rounded bodies and long necks with small heads. Like modern ostriches, these dinosaurs were extremely fast on their feet.

Dinosaurs didn't Thave two brains

Stegosaurus had a tiny brain, but at the base of its spine there was an enlarged space. Scientists once thought it might have housed a second, larger brain to control its legs, but this idea has been discredited as birds have a similar opening to store the energy-rich substance glycogen.

Pachcephalosaurs had thick skulls

Pachycephalosaur means 'thick headed lizard'. The bone at the top of their skull could be up to 25cm (10in) thick, and their faces were covered in bumps and spikes. These dramatic features could have been for fighting, or they might just have been for show, like the antlers on modern deer.

Sinornithosaurus Early Cretaceous

China

Dinosaurs had feathers Despite what you might see in textbooks, museums and even in this bookazine, we now know that most dinosaurs were not all scaly and bald. We have known for a while that the two-legged theropods had feathers, but in 2014 a very distantly related beaked dinosaur found in Siberia was also found to have feathers, suggesting scales were replaced early in dinosaur evolution.

Pterodactyls are the iconic flying dinosaurs, but they weren't actually dinosaurs at all. Dinosaurs were all land animals. Quetzalcoatlus, the largest pterosaur of all, had a 12m (39ft) wingspan,

The larger the body of an animal, the lower the surface-to-volume ratio - preventing

'Ceratopsians had horned faces

The most famous ceratopsian is Triceratops, but there were other dinosaurs with horns and frills. These huge herbivores started to appear around 160 million years ago, and it is thought the frill was used as protection against predators, to impress potential mates and as a radiator to get rid of excess heat.

All dinosaurs laid eggs
Dinosaurs all reproduced by laying eggs like modern-day birds, and some of the hatchlings were thousands of times smaller than the full-grown adults.

Some dinosaurs cared for their young

Adult Psittacosaurus have been found alongside the fossilised remains of their young, and the bones of older babies have been found in the nests of Maiasaura, indicating that they probably helped to raise their young.

The largest dinosaur egg was over 60cm long

The largest dinosaur eggs were found in Mongolia in the 1990s, and measured around 45cm (17.7ft) across. Compared to the size of the adults, they are still surprisingly small.

Some of the best dinosaur fossils are babies

A 113-million-year-old fossilised baby dinosaur found in Italy still contains traces of preserved soft tissue, including intestines and tail muscles.

Baby dinosaurs grew rapidly

Sauropods like Diplodocus weighed a tiny 5kg (11lb) at birth, and grew to 10,000 times their size within just 30 years. Fossilised embryos show sauropod bones filled with blood vessels, bringing nutrients to allow rapid growth.

There are two main 55 types of dinosaur egg

Dinosaur eggs can be divided into two main categories - spheroidal and elongated. Rounder eggs were laid by herbivores such as sauropods, while elongated, bird-like eggs were laid by theropods.

Oviraptors didn't steal eggs

The name 'Oviraptor' means egg thief, but these dinosaurs weren't criminals. They were actually devoted parents, and fossilised nests found in Mongolia show they arranged their eggs in spiral layers.

favourite prey were such as Triceratops

the Ceratopsians,

Among the T-rex's

Vramnosaurus rex

35 You probably couldn't outrun a **Iyrannosaurus**

Computer simulations of T-rex running around 29kmh (18mph). Not quite fast catch any human that's not an athlete. enough to catch up with a car, like in Jurassic Park, but quick enough to suggest that it had a top speed of

and used their tails as a counterweight,

holding them up for balance.

belonged to a group of dinosaurs known group are the largest carnivores ever to as theropods. Some members of this Frex, Allosaurus and Deinonychus have walked the Earth.

Classification Dinosaurs can be split into two major groups, with many more subdivisions

49 The meat-eating dinosaurs walked on two feet

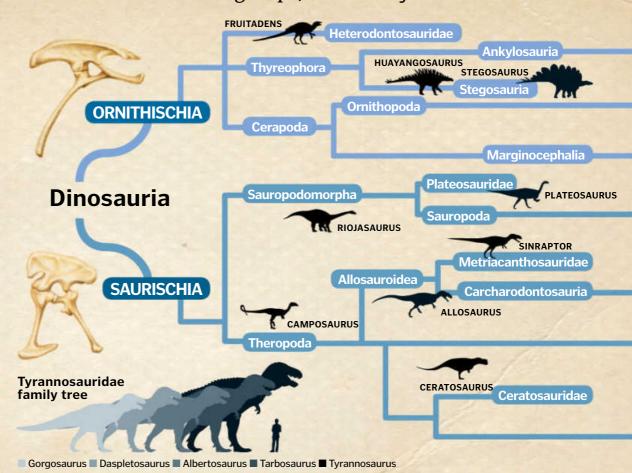

All the carnivorous dinosaurs were theropods (although not all theropods were carnivores) and walked upright on their two hind legs. They typically had hollow bones, three main fingers on each hand and foot, and sharp, curved teeth and claws used for hunting and eating.

Dinosaurs either had lizard hips or bird hips

Dinosaurs can be divided into two major groups based on their hipbones. The Ornithischia, or 'bird-hipped' dinosaurs had a pubic bone that pointed toward the tail. and the Saurischia, 'lizard-hipped' dinosaurs pointed toward the head. Interestingly, birds evolved from lizard-hipped dinosaurs.

Most dinosaurs ate plants

Dinosaurs are often portrayed as fearsome hunters, but the majority of species were herbivores. Even some of the ferocious-looking theropods actually ate plants and used their sharp claws for digging.

6 Dinosaurs lived during the Mesozoic Era

Dinosaurs ruled the Earth for 165 million years, in a time period known as the Mesozoic Era. This era can be split into three periods. Triassic, Jurassic and Cretaceous

Dinosaurs first appeared 230 million years ago

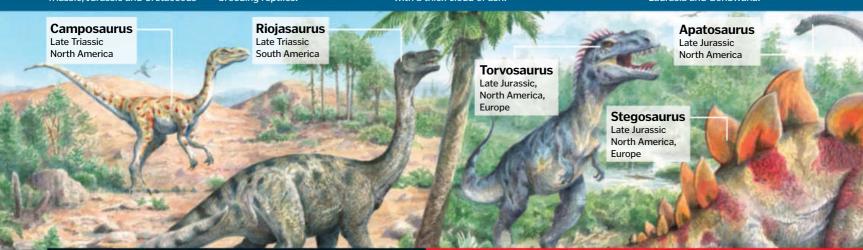

Dinosaurs evolved during the Triassic period, between 250 and 200 million years ago. The warm, dry conditions were perfect for breeding reptiles.

58 Volcanic eruptions contributed to the **Q** Volcanic eruptions extinction of the dinosaurs

Huge lava flows are present in the fossil record for about 500,000 years before the extinction of the dinosaurs, and many scientists think eruptions contributed to their extinction by filling the air with a thick cloud of ash

59Early dinosaurs lived on the continent of Pangaea

When dinosaurs first appeared, the landmasses of the Earth were joined into a supercontinent called Pangaea. This later fractured into two continents. - Laurasia and Gondwana.

TRIASSIC 252-201 MILLION YEARS AGO

JURASSIC 201-145 MILLION YEARS AGO

There were more than 700 species of dinosaur

To date, over 700 species of dinosaur have been identified, but only around 300 have been confirmed as entirely unique. There are more yet to be found, so this number will continue to change.

There are hundreds of dinosaurs yet to be found

It is estimated that we have only found around a tenth of the dinosaur species that ever existed. Some are buried in rocks we cannot reach, while others lived in areas where conditions did not favour fossil formation.

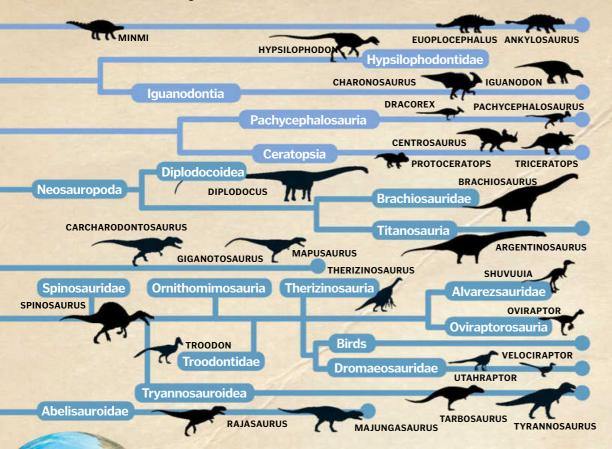

There were fewer dinosaur species than we thought

Hundreds of species of dinosaur have been named, but few baby dinosaurs have been found. Scientists have reviewed the evidence and have found that some smaller species might actually be the babies of larger species.

Ceratosaurus Late Jurassic North America, Furone

Dinosaurs are still alive today

In the 19th century the fossilised remains of a feathered dinosaur called Archaeopteryx were discovered, and since then evidence linking dinosaurs to birds has stacked up. It is thought that early birds started to evolve from the carnivorous theropods in the late Jurassic, and a few managed to survive the mass extinction, giving rise to the bird species we see today.

Sea levels were at an all-time high in the Cretaceous

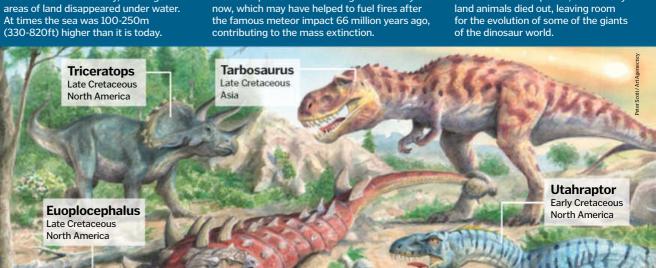

During the Cretaceous period, sea levels rose and fell dramatically, and large

High oxygen levels fuelled fires during the extinction event

During the Cretaceous period, oxygen levels in the atmosphere were much higher than they are

52They experienced more than one mass extinction

There was a mass extinction at the end of the Triassic period, when many

63 Armoured dinosaurs are known as 'Thyreophora'

Stegosaurus and Ankylosaurus are famous for their armour plating and were members of a group of dinosaurs called Thyreophora. Anklosauria were the most heavily armoured and had bony plates, spikes and clubbed tails.

4 Dinosaur's legs are positioned beneath their bodies

Crocodiles and lizards walk with their legs out to the sides, but dinosaurs have their legs underneath their bodies, allowing them to run faster.

65 Some dinosaurs swallowed rocks

Many plant-eating dinosaurs have been found with groups of rounded stones inside their ribcages, indicating they swallowed stones to aid digestion, like modern birds.

Some dinosaurs had a mixture of dinosaurlike and bird-like features

Birds are descended from small theropods. They walked upright on two legs and fossil evidence shows that some of them had feathers.

> **Caudipteryx Early Cretaceous**

67Dinosaurs lived in a changing world

Around 250 million years ago, all of Earth's landmasses were joined in a supercontinent known as Pangaea. During the reign of the dinosaurs, this landmass split apart, first into two and then into the seven continents we see today.

68 Paleontologists Study fossils

are known as palaeontologists. Anthropologists study human remains, and archaeologists study artefacts.

The longest dinosaur name

Micropachycephalosaurus means 'tiny thick-headed lizard'. It might have the

longest name, but it was only about 1m

has 23 letters

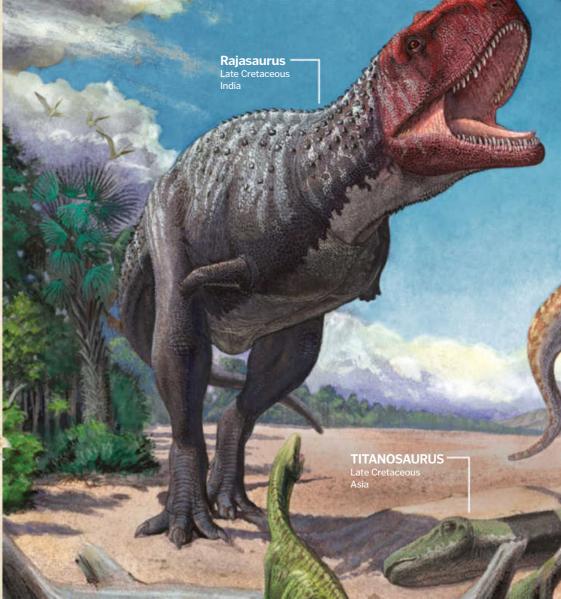

(3.3ft) long.

69 Some herbivores had Scientists that study dinosaur remains self-sharpening teeth

As their jaws closed, the teeth of some plant-eating dinosaurs would grind against each other, wearing the surface into a sharp point.

Hadrosaurs had the most teeth

The duck-billed dinosaurs had up to 50 rows of teeth stacked on top of one another, making a total of over 1,000.

Hunting dinosaurs Fossils have be found on every continent on Earth...

Ankylosaurus

Late Cretaceous North America

North America has excavated the most dinosaur fossils

North America, Argentina and China have more than their fair share of dinosaur fossils. Areas with desert-type environments prevented the build-up of thick layers of plants, leaving the remains easier to find under sand and rock

The first dinosaur fossil was found in England

The first dinosaur to be scientifically documented was Megalosaurus, formally named by William Buckland in 1824. The fossils were found in a quarry in Oxford.

Fossilised dinosaur 81 highways allow us to retrace ancient steps

Enormous mudflats captured the imprints of dinosaur footprints, and some were preserved as fossils. Utah in the United States is particularly famous for its dinosaur trackways, which can be found on what used to be an ancient muddy floodplain.

New dinosaurs Zare discovered every year

There are hundreds of dinosaur fossils still to be discovered, and a new dinosaur is found and named approximately every seven weeks.

3Chicxulub crater marks the asteroid impact that killed the dinosaurs

Chicxulub crater in Mexico is a 66 million-year-old, 180km (112mi)-wide impact created by a 10km (6mi)-wide asteroid. It is thought to represent the aftermath of the impact that killed the dinosaurs. In 2016, scientists plan to drill into the crater to learn more about its history.

4 Dinosaur bones can be recognised by distinctive skull holes

All dinosaurs have the same basic skull, with two holes for jaw muscles behind the eye and an air socket between the eyes and nose.

Giganotosaurus

Late Cretaceous South America

S5 Dinosaur bones can be aged by radiometric dating

Carbon dating doesn't work on dinosaur bones, so scientists estimate the age of fossils by measuring radioactive isotopes in the surrounding rocks.

5 Dinosaurs weren't the first reptiles to rule the Earth

Around 300 million years ago amphibians dominated Earth, but as it got warmer, reptiles took over. There were pelycosaurs, mammal-like reptiles called therapsids, and archosaurs, from which dinosaurs, crocodiles and pterosaurs evolved.

6Dinosaurs blived for up to 300 years

Paleontologists estimate the large dinosaurs had life spans ranging from 75 to 300 years. These estimates were made based on information we have on cold-blooded animals - warm-blooded creatures have shorter lives.

Troodons were probably the cleverest dinosaurs

Troodons lived around 77 million years ago and were about two metres (6.6 feet) long. They were carnivores, walked on two legs and had relatively large brains. They are also thought to be related to modern birds.

8 Amber insects don't contain dinosaur DNA

Jurassic Park is based on the idea that you could extract dinosaur DNA from blood preserved inside the bodies of mosquitoes encased in amber. Despite several attempts to recover DNA, it seems it doesn't actually survive inside the amber.
